Elective cardioversion is done under general anesthesia. Pretreatment with antiarrhythmic agents before electrical cardioversion of patients with atrial fibrillation is recommended to help prevent recurrence of atrial fibrillation after cardioversion. Unless the patient's condition is too critical to delay cardioversion, we treat for 2 weeks with amiodarone (12 to 15 mg/kg orally [PO] q24h) before the procedure. Although this antiarrhythmic agent causes pharmacologic restoration of sinus rhythm in some humans, we have not observed this in dogs. Amiodarone is continued after cardioversion at a maintenance dosage of 5 to 7 mg/kg orally every 24 hours. Preferably the cardioversion procedure should be scheduled for early afternoon so that serum levels of electrolytes may be obtained and electrolyte abnormalities corrected, if needed, before anesthesia. In addition the atria should be examined echocardiographically for thrombus in the morning on the day of the scheduled procedure. Successful cardioversion is more likely to be achieved if serum magnesium and potassium concentrations are in the mid to upper range of normal. We try to achieve a serum potassium concentration of 4.5 to 5.5 mEq/L and a serum magnesium concentration greater than 2 mEq/L immediately before cardioversion. Digoxin should be withheld on the day of the procedure; but, if digitalis toxicity is suspected, the cardioversion should be postponed until this problem has resolved.

Anesthetic premedication is recommended using an opioid (fentanyl 5 to 10 mcg/kg, hydromorphone 0.05 to 0.2 mg/kg, oxymorphone 0.05 to 0.1 mg/kg, or methadone 0.5 to 1 mg/kg) either alone or in combination with a benzodiazepine (midazolam 0.1 to 0.3 mg/kg) and administered subcutaneously or intramuscularly approximately 30 minutes before instrumentation and patient preparation. Before anesthetic induction the lateral thorax is clipped on each side from the axilla caudally and ventrally approximately 15 cm to facilitate placement and contact of the cardioversion paddles. Electrocardiographic electrodes are attached to the skin of the extremities and connected to the electrocardiographic (ECG) leads of the cardioversion device.

Anesthesia may be induced with fentanyl (5 to 20 mcg/kg), etomidate (0.5 to 2 mg/kg), or a combination

of these two drugs combined with a benzodiazepine (diazepam 0.2 to 0.5 mg/kg or midazolam 0.1 to 0.3 mg/kg). An anticholinergic agent administered at a conservative dose is indicated if the heart rate decreases enough to adversely affect cardiac output and blood pressure. Short-term maintenance of anesthesia for cardioversion may require additional doses of the induction drugs or supplementation with low doses of propofol (0.25 to 1 mg/kg).

We recommend that patients be intubated and administered 100% oxygen using a standard small animal breathing circuit. Manual or mechanical ventilation of the patient may be necessary to avoid hypoventilation and respiratory acidosis during periods of deep sedation. Heart rate and rhythm, blood pressure, oxygen saturation, and end-tidal carbon dioxide should be monitored during and immediately after cardioversion. Inhalation agents are used by some clinicians but are generally not administered in our practices unless the patient needs an additional diagnostic or surgical procedure following the cardioversion.

Although cardioversion may be done by delivery of energy through either preplaced adhesive cardioversion pads or cardioversion paddles held against the thorax, we prefer paddles to achieve optimal positioning of electrodes and minimal transthoracic impedance. Immediately following induction of anesthesia, the patient is positioned in dorsal recumbency in a foam trough placed on a padded table. The forelimbs are secured cranially, and the rear limbs are secured caudally (Fig. 164-1). Care must be taken to ensure that neither the dog nor the operator is in contact with any metallic surface.

The synchronous mode (cardioversion mode) of the cardioverter/defibrillator is selected to prevent current delivery during the ventricular repolarization phase of the cardiac cycle. When the cardioverter/defibrillator device is used in its cardioversion mode, the device should recognize QRS complexes and identify them on the monitor. To prevent improper synchronization with accidental triggering of ventricular fibrillation, the operator should verify that the device is set to synchronous mode and that it is correctly identifying R waves before delivery of *each* shock. Some units require a resetting to synchronous mode following each shock. Erroneous identification of QRS complexes by the device is more likely to occur in patients with tall, peaked T waves or splintered QRS complexes. *Electrode paste* is applied to the cardioversion paddles, and the paddles are then held against the clipped areas of the thorax with the top of the paddles at approximately the level of the point of the shoulders (see Fig. 164-1). Pediatric paddles should be used for dogs less than 15 kg. Firm pressure on both paddles should be used to provide adequate electrical contact and reduce transthoracic impedance. The operator should give an "all clear" command and verify that no assistants are touching the animal or equipment before discharging the device.

It is recommended that the initial energy setting be low (10 to 20 J for atrial flutter and 35 to 50 J for atrial fibrillation) and additional shocks delivered, when necessary, using upward titration of energy until successful cardioversion is achieved or until the peak energy output of the device has been used. If a maximal energy biphasic shock fails to restore sinus rhythm, a low dose of quinidine gluconate may be administered (0.5 mg/kg

Fig. 164-1 Photo of a dog undergoing electrical cardioversion.

intravenously [IV]) in an attempt to facilitate cardioversion, and the maximal energy shock is then repeated. Reversing paddle polarity occasionally can be helpful. Ibutilide, a class 3 antiarrhythmic agent, has been used in humans as an alternative to quinidine to facilitate electrical cardioversion of atrial fibrillation. It is important to distinguish between inability to restore sinus rhythm, indicating inadequate energy delivery to the atria, and inability to maintain sinus rhythm after transient termination of atrial fibrillation. The latter situation (early reinitiation of atrial fibrillation) does not respond to higher energy shocks but may respond favorably to intravenous quinidine (0.5 to 1 mg/kg) or procainamide (6 to 8 mg/kg) given before delivery of an additional shock.

Following cardioversion the ECG should be monitored at least until full consciousness has been restored and preferably for several hours thereafter. If frequent premature atrial contractions are noted, suppression of supraventricular ectopy with a class 1A antiarrhythmic (procainamide 10 to 20 mg/kg intramuscularly [IM]) may possibly prevent early relapse into atrial fibrillation or atrial flutter. Dogs with structural heart disease should be maintained on medications for management of heart failure; however, drugs administered solely for heart rate control (e.g., digoxin, diltiazem) are discontinued.

EFFICACY OF BIPHASIC EXTERNAL CARDIOVERSION IN DOGS WITH ATRIAL FIBRILLATION

Retrospective evaluation of data from dogs with chronic atrial fibrillation has shown that transthoracic cardioversion with a biphasic waveform is a highly effective method of restoring sinus rhythm in canine patients (Bright, Martin, and Mama, 2005). In our experience successful cardioversion is achieved in more than 90% of dogs even in the presence of severe underlying heart disease. Restoration of sinus rhythm does not appear

to be beneficially or adversely affected by pretreatment with amiodarone. In dogs undergoing biphasic cardioversion of atrial fibrillation at our hospital, the presence of underlying structural heart disease had no statistically significant effect on the current required to restore sinus rhythm. Similarly, the presence of structural heart disease did not significantly affect the total conversion energy or the conversion energy expressed as a function of body weight. The average current required to achieve cardioversion in our canine patients (mean 11.7 ± 4.5 A) was similar to the current required for biphasic transthoracic cardioversion of humans with atrial fibrillation (11 ± 1 A) (Mittal et al., 2000). This current is significantly less than that required for traditional cardioversion of humans using a monophasic energy waveform (41 ± 11 A) (Dorian et al., 2001). Fig. 164-2 shows a typical ECG strip recorded during biphasic electrical cardioversion of a dog with atrial fibrillation.

DURATION OF SINUS RHYTHM AFTER CARDIOVERSION OF ATRIAL FIBRILLATION

Antiarrhythmic agents generally are recommended to promote maintenance of sinus rhythm following cardioversion. In humans with chronic atrial fibrillation amiodarone is the most effective pharmacologic agent for maintenance of sinus rhythm (Kochiadakis et al., 2000). This drug is usually administered for 3 to 4 weeks before the cardioversion procedure. Other drugs that have proven useful for maintenance of sinus rhythm in humans include propafenone and sotalol. In dogs the importance of initiating antiarrhythmic agents before the cardioversion is debatable; however, data from our institution suggest a beneficial effect of pretreatment with amiodarone. We generally begin administration of amiodarone 2 weeks before the cardioversion procedure, but if it is not in the best interest of the patient or the owner to delay cardioversion, amiodarone

Fig. 164-2 A lead II ECG rhythm strip recorded during external electrical cardioversion of atrial fibrillation in a canine patient. The small arrows indicate QRS complexes appropriately identified by the device in its cardioversion (synchronized) mode. A biphasic shock of 100J is delivered at the large arrow. After the shock there is normal sinus rhythm (paper speed 25 mm).

is begun as soon as possible after the dog awakens from anesthesia. Thyroid function and hepatic function should be monitored (every 3 to 6 months) in dogs receiving amiodarone. Because serum amiodarone concentration does not correlate well to tissue concentration, serum drug levels are not routinely evaluated. Nonetheless, a serum amiodarone concentration below the therapeutic range may be helpful information to have when planning management of dogs with recurrence of atrial fibrillation after cardioversion. Amiodarone is continued indefinitely in dogs with underlying heart disease, particularly those with significant atrial enlargement. Because electrophysiologic remodeling of the atrial myocytes induced by atrial fibrillation is reversed after 2 to 4 weeks of sinus rhythm, consideration should be given to discontinuing amiodarone; however, the structural remodeling induced by atrial fibrillation is not completely reversible.

Although transthoracic biphasic cardioversion is a highly effective method of restoring sinus rhythm in dogs with naturally occurring chronic atrial fibrillation, the duration of sinus rhythm after cardioversion is quite variable. Unfortunately there is no consistently reliable way of determining which dogs will have an early recurrence of atrial fibrillation after electrical cardioversion. Recurrence of atrial fibrillation occurs earlier in dogs with underlying structural heart disease than in dogs with lone atrial fibrillation. Also, in a series of dogs undergoing cardioversion at our institution, those with atrial enlargement tended to have an earlier recurrence of the arrhythmia. Chronicity of atrial fibrillation before cardioversion is known to be inversely related to the duration of sinus rhythm following cardioversion in humans, and our data indicate that this relationship is valid in dogs as well. Atrial fibrillation is known to produce electrophysiologic and structural remodeling of the atrial myocardium, and this remodeling subsequently promotes both maintenance and recurrence of this arrhythmia ("atrial fibrillation begets atrial fibrillation") (Wijffels et al., 1995; Yu et al., 1999). Admittedly, the duration of atrial fibrillation before cardioversion is difficult to precisely determine in dogs, especially in dogs without underlying heart disease ("lone atrial fibrillation"). Therefore for many dogs the duration of the arrhythmia is only an estimate. Nonetheless our experience suggests that

the prognosis for long-term maintenance of sinus rhythm after cardioversion is less favorable when the arrhythmia has been present for more than 6 months.

POTENTIAL CLINICAL BENEFIT OF RESTORING SINUS RHYTHM

Treatment goals for patients with chronic atrial fibrillation are to reduce or eliminate clinical signs resulting from the arrhythmia and to prevent long-term complications. Although humans with atrial fibrillation often have impaired exercise tolerance and reduced quality of life, dogs without underlying heart disease may have no apparent clinical signs. Therefore in dogs with lone atrial fibrillation, restoration of sinus rhythm with DC cardioversion is done solely to prevent potential complications such as thromboembolism and tachycardia-induced myocardial failure. In dogs with underlying heart disease, initiation of atrial fibrillation frequently coincides with deterioration in clinical status, including the onset or the recurrence of congestive heart failure, weakness, anorexia, syncope, or collapse. Restoration of sinus rhythm, even if short term, is theoretically advantageous in these patients because of the salutary effects of sinus rhythm on ventricular filling pressures, cardiac output, heart rate, and coronary perfusion.

A controlled, prospective study is needed to confirm that rhythm control has a beneficial effect on the clinical status and survival of dogs with heart disease. However, in the meantime we have evaluated retrospectively the severity of heart failure in dogs successfully converted to sinus rhythm at our hospital. Using the International Small Animal Cardiac Health Council Heart Failure Classification to characterize the severity of clinical signs before and after cardioversion in 22 dogs, restoration of sinus rhythm was associated with reduction (9 of 22) or complete resolution (9 of 22) of clinical signs in 18 patients (81.8%). Before cardioversion 45.5% of the 22 dogs were in severe heart failure, and 54.5% were in mild- to-moderate failure. After cardioversion heart failure was severe in 0% and mild to moderate in 54.5%; 45.5% were asymptomatic. Thus preliminary data from our case series suggest that restoration of sinus rhythm

Fig. 164-3 A lead II ECG rhythm strip recorded during external electrical cardioversion of atrial flutter in a canine patient. The small arrows indicate QRS complexes appropriately identified by the device in its cardioversion (synchronized) mode. A biphasic shock of 20J is delivered at the large arrow. After the shock there is normal sinus rhythm (paper speed 25 mm/second).

is helpful for stabilizing the clinical status of dogs with heart disease and that many dogs remain in sinus rhythm long enough to benefit from the procedure.

BIPHASIC EXTERNAL CARDIOVERSION IN DOGS WITH ATRIAL FLUTTER

Although sustained atrial flutter occurs far less frequently in dogs than sustained atrial fibrillation, pharmacologic rate control is often more difficult to achieve in patients with atrial flutter. Therefore biphasic transthoracic cardioversion provides an alternative method of managing this tachyarrhythmia. We have used biphasic transthoracic DC cardioversion in six dogs with atrial flutter; and restoration of sinus rhythm was achieved in all six, with conversion energies ranging from 15 to 30J (0.4 to 1.2J/kg) and conversion currents of 3 to 5 A. Atrial flutter recurred in two of these dogs after 42 and 124 days despite the use of amiodarone. Fig. 164-3 shows the ECG strip recorded during biphasic cardioversion of a dog with sustained atrial flutter.

BIPHASIC EXTERNAL CARDIOVERSION IN DOGS WITH VENTRICULAR TACHYCARDIA

Rapid and sustained ventricular tachycardia causes severe hemodynamic compromise. In most canine patients conversion to sinus rhythm and control of ventricular tachycardia can be accomplished with drugs. Occasionally pharmacologic conversion is not possible, or the side effects of the medications needed for conversion are intolerable. In these cases synchronized electrical cardioversion can be used to restore sinus rhythm. Pretreatment with an appropriate ventricular antiarrhythmic before cardioversion is recommended except in immediately life-threatening situations.

SAFETY OF EXTERNAL BIPHASIC CARDIOVERSION

To date we have observed no clinically significant adverse effects from biphasic DC cardioversion. Minor adverse

effects noted have included brief asystole and nonsustained ventricular tachycardia immediately after shock delivery. Previous studies in dogs and other species have shown biphasic energy waveforms to be safe and minimally damaging to the myocardium. Although ventricular fibrillation has been described as a risk of traditional monophasic DC cardioversion in dogs, we have not observed this serious arrhythmia in any patient, including dogs with severe congestive heart failure and severe systolic dysfunction. We also have not observed significant adverse effects of amiodarone in our series of canine patients; however, others have reported serious adverse effects, particularly hepatotoxicity.

Patent Ductus Arteriosus

MATTHEW W. MILLER, *College Station, Texas*

SONYA G. GORDON, *College Station, Texas*

Patent ductus arteriosus (PDA) is a persistence of a fetal communication between the descending aorta and the main pulmonary artery. PDA is the second most common congenital cardiac malformation diagnosed in dogs. There is a higher incidence in females, with an odds ratio of approximately 3:1, although this is not evident in all breeds. Without correction, PDA has an estimated 1-year mortality that approaches 60%. Although subaortic stenosis (SAS) is reportedly the most commonly diagnosed congenital malformation, many diagnosed cases are of trivial hemodynamic significance, requiring no intervention and having little effect on an individual patient's life quality or duration. Therefore PDA is the most commonly diagnosed defect that routinely requires intervention.

DIAGNOSIS

The initial diagnosis of PDA still depends on careful physical examination and detection of the classic continuous murmur. In animals with very rapid heart rates or elevations in pulmonary artery pressure, the diastolic component of the murmur may not be appreciated if careful auscultation is not performed. Ensuring that the stethoscope is placed high in the left axillary region increases the likelihood of an accurate initial diagnosis. Large volumetric left-to-right shunts frequently result in femoral pulses that are hyperdynamic or bounding.

Practicing veterinarians must be able to recognize the murmur of PDA so that appropriate diagnostic tests and treatments can be offered. In addition to concentrating on the dorsal left axillary region during auscultation, slowly moving the chest piece between the point of maximal murmur intensity and the left apex often allows the examiner to appreciate the continuous nature of the murmur at the base. In some puppies and kittens the continuous murmur may be equally loud or even more prominent immediately cranial to the left edge of the manubrium. In very young puppies or kittens and in cats with developing pulmonary hypertension the murmur may be very faint to absent at end diastole.

In a very small percentage of cases severe pulmonary vascular injury leads to shunt reversal (right-to-left PDA), a condition that is not amenable to closure in any manner. Dogs tend to develop pulmonary hypertension early in life and relatively quickly from a large PDA, but the development of pulmonary hypertension in cats typically is more gradual. This allows some cats to benefit from closure of the ductus, despite the presence of pulmonary vascular disease.

Diagnostic imaging allows for characterization of the type and severity of the defect. Classic radiographic findings

include left ventricular and atrial dilation with pulmonary overcirculation, with venous prominence often evident. It is also common to appreciate dilation of both the main pulmonary artery and descending aorta. Pulmonary edema is present following the onset of congestive heart failure. A complete Doppler echocardiographic study is the test of choice for definitive diagnosis. Echocardiographic features of PDA include dilation of the left atrium, left ventricle, ascending aorta, and pulmonary artery. A portion of the PDA itself frequently can be visualized from several imaging planes, but the left cranial short axis view usually provides the optimal image. Saunders and colleagues (2007) at our institution recently described the transthoracic and transesophageal echocardiography (TEE) appearance of PDA as it relates to angiographic anatomy demonstrating the superiority of TEE for critical description of ductal anatomy in the dog. Doppler echocardiography confirms continuous flow in the main pulmonary artery with reversal of flow in diastole. Mild-to-moderate mitral regurgitation is a frequent finding, secondary to annular dilation. Depending on its severity, it usually resolves following ductal ligation or occlusion. Evidence of systolic dysfunction (elevated left ventricular internal diameter during systole, reduced percent fractional shortening) is common in dogs with large volumetric shunts and typically persists or appears worse following successful ligation or occlusion. Transaortic flow velocities commonly are accelerated and may be as high as 3.75 m/second with large shunts. This may lead to an erroneous diagnosis of concurrent SAS. Therefore caution should be used when interpreting transaortic flows in patients with large shunts.

Most patients are in sinus rhythm when the diagnosis is established. Although the electrocardiogram (ECG) often demonstrates criteria for left heart enlargement (widened P waves; increased QRS voltages), when the rhythm is normal an ECG contributes little to the overall diagnosis. An arrhythmia is the principal indication for recording an ECG in this disease. Atrial fibrillation may develop with long standing PDA, especially in larger-breed dogs, and is the most common arrhythmia seen with PDA.

Concurrent cardiac defects are relatively uncommon, but may be more likely in large-breed dogs. In our patient population approximately 9% of dogs with PDA have an additional congenital malformation, the most common of which is pulmonic stenosis.

THERAPY

Most canine patients and virtually all cats with PDA are referred for closure of the ductus. The best outcomes

with PDA closure are likely to come from experienced operators, and this should be discussed with clients. Furthermore, closure of a ductus should never be delayed until a dog is “mature” or “develops symptoms” since irreversible myocardial damage, congestive heart failure, and death are likely outcomes. Currently there are two options: surgical ligation and catheter-based closure. The latter approach represents the most important advance in PDA management over the past decade. Surgical ligation of PDA has long been considered the standard of care for left-to-right shunting PDA and is a highly successful procedure with acceptable mortality (<5%) in experienced hands. However, in 1995 Snaps and colleagues published the first clinical report describing the use of vascular occlusion coils (Cook, Inc.) for treatment of PDA in a dog. Since that time, several devices have been evaluated for ductal occlusion in dogs.

Device Occlusion of Patent Ductus Arteriosus

Following the initial report by Snaps and colleagues, numerous reports detailed the use of either free-release or detachable occlusion coils. In addition, there have been two reports of the use of the human Amplatzer ductal occluder (AGA Medical Corp.) (Sisson, 2003). The high cost of this device and the requirement for transvenous delivery will most likely preclude its routine use in veterinary medicine. More recently the Amplatzer vascular plug (AGA Medical Corp.) and now the Amplatzer canine ductal occluder (AGA Medical Corp.) have been available and evaluated in dogs (Hogan, 2006; Nguyenba, 2006). Generally these are deployed using a femoral artery catheter. Most canine patients can be treated successfully with one of these two devices (or with coils) provided the operator is experienced and the catheterization laboratory carries a sufficient inventory of devices.

All catheter-delivered devices are deployed under general anesthesia using fluoroscopic guidance following angiographic evaluation of ductal morphology. Fig. 165-1 shows a lateral radiograph with the three most commonly used occlusion devices deployed in clinical patients.

Device Selection

Selection of device type and size is substantially influenced by ductal morphology and minimal ductal diameter as determined by angiography or echocardiography. The vast majority of reports describe obtaining vascular access for angiography and device deployment

via the femoral artery. Following routine anesthesia, arterial access is obtained by surgical cutdown to the right or left femoral artery. Following insertion of a vascular introducer, an angiographic catheter or transeptal sheath is positioned in the descending aorta or directly within the PDA. Angiograms are performed in the right lateral projection by injection of 0.5 to 2 ml/kg of radiographic contrast material either via power injector with 300 to 1050 PSI pressure or by vigorous hand injection.

Angiograms are recorded and reviewed with special emphasis on ductal morphology and minimal ductal diameter (Fig. 165-2). Although ductal morphology and minimal diameter substantially influence device selection, to date no consensus recommendations for device selection have been forthcoming. In our hospital TEE is used to screen patients before surgical or catheter-based intervention. If type III ductal morphology is diagnosed (tube with no taper), especially with a minimal ductal diameter in excess of 5 mm, catheter-based occlusion is not attempted, and the patient is sent directly to surgery for ligation.

Results of Device Occlusion in Dogs

Encouraging results with the various devices have been reported. The greatest number of cases and longest follow-up are available for patients in which vascular occlusion coils were used. The largest published study to date reported the results of 125 cases seen at a single institution (University of California, Davis) (Campbell et al., 2006). Coils were successfully deployed in 108 dogs (86%). Patients in which coil occlusion was not successful had significantly larger minimal ductal diameters than in those in which coil occlusion was successful, but specific ductal morphology was not described in this report. Complete ductal occlusion was documented in 61% of the dogs evaluated longer than 1 year following the procedure. Based on echocardiographic examination the residual ductal flow in the vast majority of the other 39% appeared to be hemodynamically inconsequential, such that repeat intervention was thought to be indicated in only four dogs (3.7%). The most common complication with the procedure was coil embolization of other vessels (n=27). There were three fatalities associated with the procedure.

Our group's experience is somewhat similar. From 1994 to 2005 we attempted coil embolization in 228 dogs. Ten procedures were aborted: seven because of an excessively large ductal diameter and three from inability to

Fig. 165-1 Lateral radiographs from dogs with patent ductus arteriosus treated with (A) multiple vascular occlusion coils, (B) Amplatzer vascular plug, and (C) Amplatzer canine ductal occluder.

Fig. 165-2 Proposed angiographic classification scheme for canine patent ductus arteriosus.

obtain adequate arterial access because of small patient size. There were two fatalities, one caused by aortic rupture and one from aortic embolization and occlusion. Residual ductal flow was substantial enough to require a repeat procedure in three patients. Nonfatal complications included pulmonary coil embolization (nine), aortic embolization (four), and partial aortic deployment and femoral artery hematoma (four). All patients in which a femoral arterial hematoma developed underwent percutaneous arterial access. Follow-up longer than 6 months was available in 117 dogs. Of these dogs only 12% had residual flow. Based on this experience we do not attempt catheter-based occlusion in patients less than 2.5 kg despite that fact that success in this patient population has been reported. In addition, in patients with large, tubular (angiographic type III) ductal morphology we prefer surgical ligation for closure.

Achen and colleagues (2006) reported successful deployment of the Amplatzer vascular plug for closure of PDA in 29 of the 30 dogs in which it was attempted. Of these 29 dogs 22 had complete occlusion 24 hours after deployment, with complete occlusion documented in an additional

two dogs within 4 months of deployment. Of the five dogs with residual flow, two had trivial-to-mild flow and no continuous murmur, and three were lost to follow-up. The plug embolized to the pulmonary vasculature in one dog (first dog), and that ductus was subsequently occluded with multiple vascular occlusion coils.

Hogan and colleagues (2006) reported successful deployment of the Amplatzer vascular plug in eight dogs without complication. Complete occlusion was achieved in seven dogs, and one dog had moderate residual flow. Smith and Martin reported (2007) complete occlusion in four of six dogs in which they deployed an Amplatzer vascular plug.

In 2006 Nguyenba and Tobias reported the initial clinical experience with the Amplatzer canine ductal occluder in 11 dogs. The device, specifically designed for dogs, was deployed successfully in 10 dogs. In one dog the device was undersized and embolized to the lung. The ductus was subsequently occluded using a larger device. Follow-up angiography in these dogs documented trivial residual flow in one case and complete occlusion in the remaining cases. No residual flow was detected by echocardiography 3 months after deployment in any of the six dogs evaluated at the time of presentation of this study.

Surgical Ligation of Patent Ductus Arteriosus

Despite the substantial advances in catheter-based interventions, surgical ligation of PDA should not be viewed as a less desirable option. In the hands of talented and experienced surgeons the success rates for ductal ligation approach 95%, with most institutions reporting mortality rates of less than 2% to 5%. Furthermore, surgical ligation can be performed with all ductal morphologies and in dogs of all sizes. For most cats surgery is probably the method of choice for closure because of the small feline size and unacceptably high embolization rates with coils. Currently catheter-based occlusion is not feasible in dogs less than 3 pounds and is difficult or not possible in all dogs less than 5 pounds or in dogs of any size with a type III ductal morphology (tube with no taper).

To our knowledge there is only one publication comparing the results of catheter-based versus surgical ligation at a single institution (Goodrich et al., 2007). In this study patient age, weight, gender distribution, and procedure times were similar for both groups. Initial success rate was higher for surgical ligation (94%) than with coil embolization (84%). There was no statistically significant difference in mortality between surgical ligation (5.6%) and catheter-based occlusion (2.6%), but this numeric difference requires more study in larger populations. It should also be emphasized that these techniques are not mutually exclusive. For example, Fujii and colleagues (2006) reported the successful use of vascular occlusion coils to occlude residual flow following surgical ligation.

Complications of Ductal Closure

The frequency of major complications in the Goodrich and colleagues study in 2007 comparing surgical ligation and catheter-based techniques showed a higher complication rate with surgery (12% versus 4.2 %). Major surgical

complications included inadvertent damage to the left cranial lung lobe, necessitating partial or complete lung lobectomy; severe ductus hemorrhage; cardiac arrest; respiratory insufficiency requiring ventilatory support; mesenteric torsion; and chylothorax. Major catheterization complications included hemorrhage associated with the femoral arteriotomy, hemorrhage secondary to inadvertent aortic perforation, and cardiac arrest at anesthetic induction.

Minor complications were more prevalent with catheter-based techniques (i.e., 26% in contrast to 12% for surgical ligation). Minor catheterization complications included inadvertent pulmonary or systemic coil embolization, partial aortic coil protrusion, ligation of both femoral arteries, femoral arteriotomy infection, and transient hemoglobinuria and thrombocytopenia. Minor complications associated with surgery included left thoracic limb lameness, suture reaction, postoperative hypoxia, incisional seroma, and minor hemorrhage.

FUTURE DEVELOPMENTS

PDA is arguably the most important congenital cardiac abnormality in dogs. Advances in catheter-based intervention make this therapeutic modality a practical alternative for all but a very small percentage of canine patients. Further technical improvements should ultimately provide the veterinary cardiologist with devices and techniques that will allow effective and safe occlusion of all ductal morphologies in any size patient. We can all look forward to ongoing advances in the growing field of interventional cardiology.

Ventricular Septal Defect

REBECCA E. GOMPE, *Knoxville, Tennessee*

JOHN D. BONAGURA, *Columbus, Ohio*

A ventricular septal defect (VSD) is a hole located in the (intra)ventricular septum that allows blood to communicate between the left and right sides of the heart. Essentially all VSDs in dogs and cats are present at birth. The prevalence of VSDs has been estimated to be 7% of dogs and 15% of cats with congenital heart defects. West Highland white terriers, Lakeland terriers, English bulldogs, and English springer spaniels are among the breeds considered at increased risk for VSDs. There are probably both national and regional differences in breed risk for VSDs. This malformation has been identified in isolation and in conjunction with other defects. In closely related English springer spaniels VSD was inherited, but the inheritance pattern was not determined. The finding of a VSD in many breeds is so sporadic that it is difficult to determine if the defect is genetic or simply a failure of normal embryogenesis. Generally no sex predilection has been noted for the development of VSD.

PATHOLOGY AND PATHOPHYSIOLOGY

Most VSDs are located dorsally in or around the membranous portion of the intraventricular septum. The typical defect is “high” and perimembranous, but there are certainly variations in location; appreciation of this point is relevant to auscultation, echocardiographic diagnosis, and catheterization or surgical intervention. The typical VSD is located just below the base of the right or noncoronary cusp of the aortic valve when viewed from the left surface of the ventricular septum. On the right side of the septum the defect is usually adjacent to the cranial edge of the septal tricuspid valve leaflet and just caudoventral to the supraventricular crest that separates the inflow from the outflow tracts. These defects are commonly classified as *perimembranous* or *paramembranous* and in older nomenclature were termed *subcrystal* defects. A paramembranous defect can be very large, as with tetralogy of Fallot, encroaching on the supraventricular crest by extending toward the right ventricular outflow tract. Other subaortic defects communicate with the supracrystal, subpulmonic portion of the ventricular septum. These holes are termed *supracrystal*, *outlet*, *subarterial*, or *doubly-committed* defects, depending on the source. A defect located immediately ventral to the septal tricuspid leaflet is typical of an endocardial cushion defect, a malformation seen most often in cats in conjunction with an atrial septal defect and a common atrioventricular valve leaflet. Defects of the muscular or trabecular ventricular septum are encountered infrequently in dogs and cats, but can be single or multiple and apical or mid-ventricular in location.

The clinical significance of the VSD depends on its size, location, and accompanying malformations. An uncomplicated, isolated VSD leads to left-to-right shunting. Blood flows at high velocity across the defect, moving from the higher-pressure left ventricle into the lower pressure right ventricle. The shunt flow usually enters adjacent to or just below the tricuspid valve. The velocity of shunting typically exceeds 4.5 to 5 m/second, as predicted by the trans-ventricular pressure difference of approximately 100 mm Hg. This flow creates a prominent systolic murmur and the disturbed spectral and color-flow pattern in the right ventricle evident by Doppler echocardiographic studies. The shunt volume crosses the right ventricular outflow tract into the pulmonary artery, using the right ventricle largely as a conduit. From there the extra volume flows into the lungs and returns to the left heart, leading to left-sided volume overload. Small-to-moderate VSDs create cardiomegaly but clinically insignificant volume overload of the left heart. However, with larger defects the recirculated blood considerably increases left atrial and ventricular diastolic volumes and pressures, leading to left heart dilation and sometimes to left ventricular failure. As a result of the increased diastolic volume and associated increase in wall tension, compensatory hypertrophy of the left ventricle occurs over time.

When left-to-right shunts are large or complicated by other left heart defects, left-sided or biventricular congestive heart failure (CHF) may develop. This is especially likely when pulmonary artery flow is 2.5 to three times greater than aortic flow or when substantial aortic or mitral regurgitation is also present. In general, an isolated VSD in a dog or cat does not commonly cause CHF unless the VSD diameter is greater than 60% to 70% of the aortic diameter, and heart failure is more often diagnosed in cats than in dogs. Seemingly most puppies with an uncomplicated defect that survive to see a veterinarian for a first vaccine are “naturally selected” to live a relatively normal life span. This probably relates to the fact that a large VSD should cause CHF very early in life, at the time pulmonary vascular resistance drops. When CHF develops before 6 weeks of age, the consequences are those of a “fading puppy” or one that appears to have died of pneumonia. However, CHF can occur in older puppies or even later in life. This is especially likely when a large paramembranous or a subarterial VSD allows the aortic root to prolapse. The subsequent loss of valvular support can allow progressively severe aortic regurgitation. This additional volume overload to the left ventricle predisposes to CHF.

The effects of a VSD on the right heart and pulmonary circulation are variable and related to defect size and

location, pulmonary valve function, pulmonary vascular reactivity, and ventricular myocardial response. Generally speaking, the larger and less restrictive a VSD, the more likely the two ventricles will function as a common chamber with systolic and diastolic pressures beginning to equalize. This situation promotes significant right ventricular enlargement and hypertrophy. If right ventricular outflow is normal and pulmonary vascular resistance remains low, there is marked left-to-right shunting with pulmonary overcirculation. This increases the likelihood of left-sided or biventricular CHF. Pulmonary hypertension can occur in this setting, but it is mainly related to increased pulmonary blood flow along with left heart failure. Radiographs show a dilated main pulmonary artery and prominent pulmonary vascularity. In other animals with large shunts, the increased pulmonary blood flow damages the vasculature, increasing pulmonary vascular resistance markedly (Eisenmenger's physiology). This leads to high-resistance pulmonary hypertension, which increases the pressure load on the right ventricle and creates a thickened chamber. This reduces left-to-right shunting and promotes bidirectional or predominantly right-to-left shunting. In these cases the proximal pulmonary arteries may be dilated, but the peripheral vascular tree appears undercirculated radiographically. These patients develop clinical signs similar to those observed with tetralogy of Fallot described briefly in the following paragraph.

Although this chapter is focused on the isolated VSD, other cardiac lesions may be evident that alter the pathophysiology, clinical findings, and management approaches. In addition to severe aortic regurgitation and Eisenmenger's physiology described previously, two other obstructive conditions of the right ventricle can complicate a VSD. One of these is the tetralogy of Fallot, in which a large unrestricted VSD is complicated by right ventricular outflow tract obstruction and severe concentric hypertrophy of the ventricle. The second condition is the so-called double-chamber right ventricle, which is characterized by fibromuscular reaction and proliferation within the right ventricular cavity. This creates a midventricular obstruction just distal to the VSD in most cases, and the proliferation may actually close the defect, leaving only midventricular obstruction. Progressive tissue growth can cause severe obstruction, and high pressures in the proximal right ventricle lead to concentric hypertrophy in the proximal chamber. In both cases right-to-left or biventricular shunting may predominate. As a result of right-to-left shunting, both hypoxemia and secondary polycythemia can develop. A similar situation can occur in dogs or cats with VSD and severe pulmonic valvular stenosis or in the rare case in which the flow turbulence promotes progressive subpulmonic obstruction.

DIAGNOSIS

Signalment and Clinical Findings

Most cases of VSD are identified during the initial vaccination examination of puppies and kittens. Any breed may be affected; but English springer spaniels, West Highland white terriers, and Lakeland terriers seem predisposed.

In cats VSD is one of the more common congenital heart defects.

Most puppies and kittens with VSD are asymptomatic. However, puppies with large defects or with significant pulmonary hypertension are likely to have signs related to exercise intolerance. Respiratory problems such as coughing and dyspnea may indicate left heart failure. Cats with CHF are lethargic and dyspneic. Puppies with biventricular failure may develop ascites, whereas kittens are more likely to show pleural effusion.

The physical examination is remarkable for the presence of a murmur that is typically loud and often associated with a precordial thrill. Blood forced through a small VSD during systole causes turbulence in the right ventricular outflow tract and pulmonary artery, which is heard as a harsh, blowing systolic murmur over the right sternal border (just ventral to the tricuspid area). The murmur can radiate widely, including to the mitral area. In subpulmonic defects the murmur is louder at the left cranial sternal border and over the pulmonary artery. A VSD can close partially or fully because of adherence of the septal tricuspid leaflet or tissue proliferation; and during this process the shunt flow may be diverted caudally or cranially, leading to systolic murmurs in unexpected precordial locations. This finding is also the case when double-chamber right ventricle complicates a VSD. In larger defects there may also be a harsh, systolic murmur over the lower left base (pulmonic area) because of relative pulmonic stenosis caused by an increased volume of blood flowing through a normal-size valve. A diastolic murmur over the left heart base indicates aortic regurgitation caused by prolapse of the aortic valve.

Radiography

The size and shape of the heart on thoracic radiographs varies, depending on the size of the VSD. With small VSDs there is mild left atrial and left ventricular enlargement with some overcirculation of the lungs, which is seen as enlarged pulmonary veins and arteries and prominent small vessels (that may be misinterpreted as increased interstitial opacities). As the size of the VSD increases, so does the size of the left heart, and the right heart becomes more likely to enlarge as well. Pulmonary overcirculation should be commensurate with the magnitude of shunting but can be reduced by reactive pulmonary vascular change. The main pulmonary artery and lobar branches are dilated with high shunt volumes or in cases of pulmonary hypertension. With high-resistance pulmonary hypertension, the main pulmonary artery segment and proximal pulmonary arteries are dilated but the smaller vessels or veins are not.

Echocardiography and Doppler Studies

The changes found on the echocardiogram also depend on the location and size of the VSD, pulmonary vascular resistance, and accompanying lesions (see Pathology and Pathophysiology earlier in the chapter). The larger the VSD, the greater the volume overload of the left heart and the greater the dilation of the left ventricle and left atrium. With moderate-to-large VSDs, there is

usually right heart enlargement as well. Right ventricular hypertrophy occurs when pulmonary vascular pressures increase and in cases of concurrent right ventricular outflow or midventricular obstruction.

The left heart responds to a chronic volume overload by dilating and then hypertrophying so that the thickness of the left ventricular wall and septum may be normal or slightly increased on echocardiography. The fractional shortening may increase initially in response to the left ventricular volume overload. However, a moderate-to-severe chronic volume overload of the left heart eventually results in decreased fractional shortening because of left ventricular dysfunction.

Imaging of an isolated VSD generally can be accomplished in the long axis view with the defect located just below the aortic valve on the left ventricular surface of the septum. On the right side the VSD is usually just ventral to the septal insertion of the tricuspid valve. The edges of the defect are sometimes quite bright. The short axis view at the base of the aorta should be used to decide where the defect enters the right ventricle. In cases of subarterial (subpulmonic) defects, the hole is not evident in long axis images but should appear readily in short or angled views.

To prevent misinterpretation of “echo drop-out,” Doppler studies should be used to confirm the presence of the VSD, especially small lesions. Color is also best for finding muscular or apical defects. For a paramembranous defect, the long- or short-axis views from the right side show a jet of blood moving toward the transducer. On the short-axis view disturbed flow is also observed in the right ventricular outflow tract during systole.

Continuous-wave (CW) Doppler can measure the velocity of the blood flow through the VSD. The smaller the VSD, the higher the velocity of flow because of the greater differences in systolic pressures between the left ventricle (≈ 120 mm Hg) and the right ventricle (≈ 20 mm Hg). This usual 100 mm Hg pressure differential between the two ventricles produces a CW velocity of around 5 m/second, assuming good alignment to flow and no obstructive lesions on the right side that would increase right ventricular pressure. Small VSDs that maintain a normal pressure gradient and create little hemodynamic burden are generally called *restrictive* defects. Low-velocity diastolic shunting is also observed in most cases. The larger the VSDs, the smaller the pressure difference between the ventricles. The velocity of blood flow crossing a large VSD is much lower. Thus the peak shunting velocity of the blood flow through the VSD on CW Doppler is used to help define the size of the VSD.

The degree of pulmonary hypertension with a large VSD can be estimated by subtracting the pressure gradient across the VSD from the systemic blood pressure. The estimate of the right ventricular systolic pressure is equal to the pulmonary artery systolic pressure if pulmonic stenosis is not present. Pulmonary artery pressures less than 30 mm Hg are insignificant. Pressures of ≈ 50 to 80 mm Hg indicate moderate pulmonary hypertension, and pressures greater than 80 mm Hg indicate severe pulmonary hypertension.

Doppler studies should also interrogate any aortic regurgitation or right ventricular obstruction. These complicated cases are best referred to a cardiologist for assessment.

Cardiac Catheterization

Cardiac catheterization is rarely done to diagnose VSD today. However, if a dog is being considered as a surgical candidate, a catheterization may be done to document pulmonary vascular resistance and pulmonary-to-systemic flow ratio. Angiocardigraphy can further delineate the anatomic location of the VSD. Catheterization procedures are also needed for interventional device closure in which various clam shell or disc devices are used to close the defect without surgery.

TREATMENT

As stated previously, the vast majority of dogs and cats that survive to the first vaccine are unlikely to develop CHF or other complications such as pulmonary vascular disease. Double-chamber right ventricle can occur as a late complication. Patients are best evaluated at least once by a cardiologist, especially when there are complicated anatomic or physiologic issues. Medical therapy and surgical or catheter-based treatments are possible but rarely needed. Some VSDs close spontaneously, often associated with an adherence of the septal tricuspid leaflet or fibromuscular proliferation. Such closure can also create a ventricular septal aneurysm that generally causes no clinical consequence.

Medical Therapy of Ventricular Septal Defects

Small VSDs do not require therapy. Dogs and cats with moderate-to-large VSDs that are not in heart failure can be started on enalapril (0.25 to 0.5 mg/kg q12h) empirically as cardioprotection. However, there are no data to support benefits of such therapy. Patients with left heart failure or biventricular failure should be treated as any other volume-overloaded hearts with furosemide, enalapril, spironolactone, and pimobendan or digoxin (see Chapter 171). These patients are also candidates for pulmonary artery banding or more definitive repair.

Dogs with significant pulmonary hypertension due to high vascular resistance are very difficult to treat because the lung damage is not often reversible. Sildenafil (Viagra, 1 to 3 mg/kg orally [PO] q12h) may be helpful in some cases of pulmonary hypertension, but the benefit in dogs with pulmonary hypertension caused by large VSDs is unknown. If prescribed for clinical signs such as exercise intolerance, improvement should be noticed within 2 to 4 weeks.

Surgical Therapy of Ventricular Septal Defects

The two surgical options for VSDs are pulmonary artery banding, which reduces left-to-right shunting and the risk of CHF, and definitive closure of the defect. Pulmonary artery banding should be done only after consultation with a cardiologist. It is important to band for evidence of severe shunting or incipient CHF, not simply cardiomegaly, which occurs with even small-to-moderate left-to-right shunts. Definitive closure of a VSD requires open heart surgery using a right atrial or right ventricular

approach, and this is limited to only a few referral centers. For more details see Section VIII on Evolve.

Transcatheter Closure of Ventricular Septal Defects

Several reports (Fujii et al., 2004; Shimizu et al., 2005) have detailed successful closure of small-to-moderate perimembranous VSDs with various transcatheter devices. Although detachable coils designed for closure of patent ductus arteriosus have been used, it is uncertain whether such defects even require closure. For larger, more significant holes, transcatheter devices with two discs are used. These can be delivered in larger dogs using traditional catheterization methods or through “hybrid” procedures in which a thoracotomy is used to deliver the system across the ventricle, but without need for cardiopulmonary bypass.

Management of Right-to-Left Shunting Ventricular Septal Defect

When VSD is complicated by right ventricular outflow obstruction or high pulmonary vascular resistance, CHF is rare; exercise intolerance, reversed shunting with hypoxemia, and polycythemia are more likely outcomes. Often animals with a sedentary lifestyle tolerate this disease for 5 or more years. Exercise creates vasodilation in skeletal muscle and increases tissue oxygen demands; accordingly, most affected animals have signs of tachypnea and exercise intolerance with exertion. Sudden death is common consequent to progressive hypoxemia, polycythemia, and cardiac arrhythmias. Any drug that causes systemic vasodilation should be avoided in these patients because right-to-left shunting can be exacerbated.

β -Blockage with the nonspecific β -blocker propranolol (starting at 0.25 mg/kg PO q8h and up-titrating over 4 weeks to 1 mg/kg PO q8h) may be beneficial by reducing exercise-induced right ventricle hypercontractility in tetralogy of Fallot since dynamic right ventricular outflow obstruction can be present. Theoretically the β_2 -blocking effect should benefit by preventing some exercise-induced peripheral vasodilation.

Definitive surgical treatment for tetralogy of Fallot includes closure of the VSD and removal or bypass of the stenosis under cardiopulmonary bypass. Palliative surgery involves creation of an extracardiac shunt between the systemic and pulmonary circulations (e.g., Blalock-Tausig

shunt). Such shunts increase pulmonary flow, improve arterial saturation, and can produce significant clinical improvement. The major limitation is the extent to which these shunts will remain patent. Aspirin or another drug that inhibits platelet activation (such as clopidogrel) is indicated. Shunts are not an option when a reversed VSD is caused by pulmonary hypertension because the high pulmonary resistance obviates the value of the surgically created shunt. Partial balloon valvuloplasty of a stenotic pulmonary valve can reduce right ventricular pressures, but complete resolution of the pulmonic stenosis allows marked left-to-right shunting and will likely be fatal.

Medical management of polycythemia associated with right-to-left shunting may be necessary. Phlebotomy can be useful. A packed cell volume of 62% to 65% often is well tolerated, but values exceeding 68% to 70% are likely to cause exercise difficulties or predispose to thrombotic stroke or sudden death. When the need for phlebotomy becomes too frequent, bone marrow suppression can be attempted using hydroxyurea (10 to 20 mg/kg PO daily). This therapy may not work; and side effects, including anorexia, gastrointestinal disturbances, and skin rash can limit tolerability of the drug. A complete blood count and platelet count should be performed regularly when treating with this drug.

Pulmonic Stenosis

AMARA ESTRADA, *Gainesville, Florida*

Pulmonic stenosis (PS) is one of the most common congenital heart defects seen in dogs. Obstruction can occur anywhere along the right ventricular (RV) outflow tract into the main pulmonary artery. The lesion can be subvalvular, valvular, or supra-valvular. Pulmonary valvular stenosis caused by commissural fusion of thin to moderately thickened valves that creates a dome-shaped valve is one type of PS. However, valvular stenosis caused by pulmonary valve dysplasia is different from the fused valve with a central orifice. Valvular dysplasia consists of markedly thickened valve leaflets with or without annular hypoplasia and fusion of the commissures. Most commonly, both types of stenosis are found to coexist whereby the valve is clearly dysplastic, but also exhibits degrees of commissural fusion. Pulmonary valvular stenosis can also occur in combination with a subvalvular fibrous or supra-valvular ring. In English bulldogs and boxers, subvalvular stenosis may be caused by an anomalous origin of the left coronary artery. In these patients a single large coronary artery originates from the right aortic sinus (of Valsalva) and then divides into the left and right main branches. The left coronary artery then encircles the main pulmonary artery just below the valve, causing a subvalvular obstruction.

DIAGNOSIS

The diagnosis of PS can be made with reasonable certainty using knowledge of breed predilection, physical examination findings, and some simple diagnostic tools found in most veterinary hospitals. A presumptive diagnosis can easily be made following physical examination and electrocardiographic and radiographic evaluations. After this, echocardiography is used to make a definitive diagnosis, determine disease severity, identify any concurrent cardiac abnormalities, and guide treatment recommendations.

Breeds Affected

PS is most commonly encountered in terrier breeds, English bulldogs, Samoyeds, Chihuahuas, miniature schnauzers, Labrador retrievers, mastiffs, chow-chows, Newfoundlands, basset hounds, and cocker spaniels and is inherited in the beagle.

Clinical Signs

Most dogs with PS are asymptomatic as puppies. Most often auscultation of a cardiac murmur during a routine examination is the first clue that PS might be present. Clinical signs are more likely to occur in dogs older than

1 year of age. Symptoms may develop earlier in dogs with extremely severe stenosis or with the presence of other congenital cardiac abnormalities such as a patent foramen ovale (PFO), atrial septal defect (ASD), ventricular septal defect (VSD) or tricuspid valve dysplasia.

Initial clinical signs are related to low cardiac output, including exercise intolerance and shortness of breath. Dogs with extremely severe stenosis can have exertional dyspnea and syncope caused by the inability of the right ventricle to increase its output in response to exercise or excitement. Arrhythmias and reflex-mediated syncope are other causes for collapse; sudden death is a rare complication but has been reported. Signs of right-sided congestive heart failure (ascites, peripheral edema, pleural effusion) usually occur later in the course of the disease but can occur earlier in patients with concurrent tricuspid valve dysplasia or with development of atrial fibrillation. Right-to-left shunting of blood can occur in patients with an atrial or ventricular communication such as a PFO, an ASD, or a VSD. Cyanosis and polycythemia are usually minimal unless a large defect is present. Growth is usually normal in patients with PS, regardless of the severity of the obstruction.

Physical Examination Findings

Auscultation of a dog with PS allows detection of a left-sided systolic murmur heard best at the heart base. In general, the intensity of the murmur increases with the severity of obstruction. The murmur is described as a classic ejection-sounding, harsh murmur with a crescendo or crescendo-decrescendo quality. Rarely a diastolic murmur of pulmonic insufficiency can also be heard. Occasionally a pulmonary ejection click is heard. The click corresponds to the time when the doming pulmonary valve reaches its open position and snaps open. Jugular veins are usually normal in dogs with PS, but a prominent A wave is sometimes observed. However, with concurrent tricuspid valve dysplasia moderate-to-severe jugular distention or pulses can be identified. In cases with concurrent tricuspid dysplasia a murmur is also auscultated over the right apical region. The murmur associated with tricuspid valve insufficiency is more blowing in character than the PS murmur. Femoral pulse quality is usually normal in dogs with PS.

Electrocardiographic Findings

The electrocardiogram (ECG) may be normal in dogs with mild PS and therefore may be somewhat useful in assessing severity of obstruction. Dogs with more moderate-to-severe PS and RV hypertrophy usually have

electrocardiographic evidence of right-sided enlargement (right axis deviation; deep S waves in leads I, II, III and aVF; prominent S waves in left-sided chest leads).

Radiographic Findings

Thoracic radiographs are very useful for supporting the clinical diagnosis of PS. However, it should be noted that, just as with the ECG, radiographs in mild cases of PS may be completely normal. Radiographs in dogs with moderate-to-severe PS usually demonstrate a prominent right ventricle and poststenotic dilation of the main pulmonary artery. Poststenotic dilation of the main pulmonary artery can be seen on a lateral view but is most impressive on a dorsoventral view. The pulmonary vasculature and parenchyma are usually normal, although sometimes they may appear undercirculated, especially in cases of right and left shunting.

Echocardiographic Findings

Obstruction in the RV outflow tract causes an increased resistance to flow and an increase in RV systolic pressure. The magnitude of increase in RV pressure depends on the severity of obstruction. The more severe the stenosis, the more pressure the right ventricle must generate to overcome the stenosed valve and maintain pulmonary perfusion. The response of the right ventricle to this pressure overload is concentric hypertrophy.

Two-Dimensional Echocardiography

Two-dimensional echocardiography allows for subjective evaluation of the severity of stenosis. Typical features of PS can be demonstrated clearly from both the right-sided long-axis and short-axis views (Fig. 167-1). In general, the thicker the right ventricle, the more severe the stenosis is likely to be. Concentric hypertrophy of the

right ventricle, narrowing in the region of the pulmonary valve, and poststenotic dilation of the pulmonary artery are hallmarks of PS. In severe cases septal flattening may occur as RV systolic pressure becomes higher than left ventricular systolic pressure (see Fig 167-1). Dogs with severe PS may also have hyperechoic regions visible within the right ventricle or septum related to areas of ischemia and fibrosis.

Three features of valvular stenosis that occur to varying degrees are: fusion of leaflets, valve thickening, and hypoplasia of the annular region. Valve leaflets may appear prominent because of thickening. Systolic motion of the valve leaflets is restricted, with inward curving of the tips of the leaflets known as *doming* apparent in stenosed but mobile valves. Dysplastic valves often appear very thickened and can be immobile, without the characteristic doming seen with the “typical” valvular stenosis of children. Poststenotic dilation of the pulmonary artery may be absent, and the pulmonary annulus may be hypoplastic in cases of valve dysplasia. The distinction between the two types of stenosis is often not clear, and pathologic features of both forms are usually present. For prognostic reasons dysplastic valves should be assessed for mobility, commissural fusion, and hypoplasia. Hypoplasia and immobile valves are likely to respond less favorably to interventional therapy.

Evidence of dynamic infundibular stenosis caused by hypertrophy may also be seen on two-dimensional evaluation. During systole, as the walls of the hypertrophied infundibulum come together, obstruction in this region can occur in addition to the valvular obstruction (Fig. 167-2). The severity of this dynamic stenosis may be impossible to estimate, but it is important to identify it before interventional procedures because this type of stenosis can become acutely more severe following balloon valvuloplasty and may require β -adrenergic blockade (see discussion of suicide right ventricle in the section on Therapy later in the chapter).

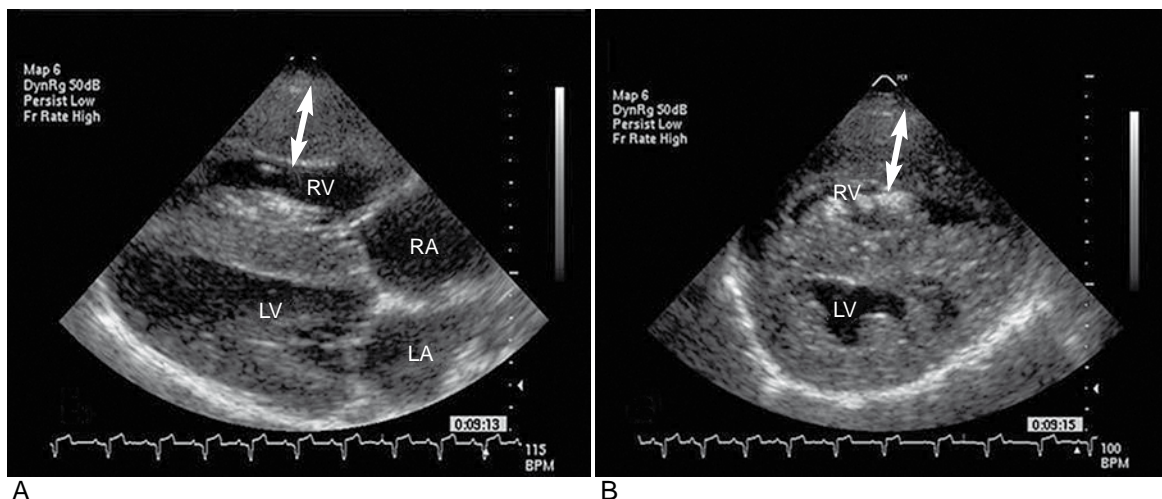

Fig. 167-1 Echocardiographic images from a dog with severe pulmonic stenosis. **A**, Right-sided four-chamber long-axis view, and **B**, right-sided short-axis view. Both echocardiographic images show dramatic right ventricular hypertrophy (arrows) and evidence of septal flattening, indicating higher right than left ventricular pressure. Notice also the increased echogenicity of the papillary muscles of the right ventricle, indicating probable ischemia of this portion of the myocardium. This degree of hypertrophy and septal flattening would be a typical appearance for a dog with severe pulmonic stenosis.

Fig. 167-2 Echocardiographic images from a dog with severe pulmonic stenosis; short axis images obtained at the level of the pulmonary valve. The pulmonary valve is severely thickened and dysplastic. There is no evidence of poststenotic dilation of the pulmonary artery beyond the dysplastic valve. The annulus is normal in size. During diastole (**A**) the infundibular or subvalvular region is open without evidence of subvalvular obstruction. However, during systole (**B**) the walls of the hypertrophied infundibulum come together and may create a dynamic subvalvular obstruction (arrow). In some patients with significant infundibular hypertrophy, this subvalvular gradient can become acutely more severe following dilation of the stenosed pulmonary valve. This condition, termed *suicide right ventricle*, can occur immediately following balloon valvuloplasty. Right ventricular pressures dramatically increase as the hypertrophied infundibulum creates subvalvular obstruction that can sometimes become worse than the valvular obstruction.

Doppler Evaluation

Doppler echocardiography is useful in readily visualizing the turbulence that is created as blood flow encounters the stenosed valve. It can also help in recognizing dynamic obstruction, pinpointing exact locations of obstruction, and identifying any pulmonic insufficiency present. However, the major use of Doppler echocardiography is in determining the velocity of blood flow as it crosses the stenosed valve. Two-dimensional echocardiography allows for subjective and qualitative assessment of severity, whereas Doppler allows objective and quantitative assessment of the severity. Using the modified Bernoulli equation

$$\Delta \text{ pressure} = 4V^2$$

the measured velocity across the stenosed valve can be calculated into a pressure gradient across the valve. Gradients can be thought of as the difference in pressure between two chambers. In a normal dog without PS there is essentially no gradient across the pulmonary valve since systolic pressure in the right ventricle is equal to systolic pressure in the pulmonary artery. However, when the pulmonary valve is stenosed, the RV must generate enough pressure to overcome the obstruction and maintain pulmonary blood flow and systolic blood pressure.

For example, in a dog with PS, a velocity of 5.5 m/second is recorded (Fig. 167-3). This is calculated to equal a gradient of 121 mm Hg ($\Delta \text{ pressure} = 4(5.5)^2 = 121 \text{ mm Hg}$). Assuming that PA pressures are normal at about 25 mm Hg (121 mm Hg + 25 mm Hg), the right ventricle has a pressure burden of 146 mm Hg (versus a normal systolic pressure of 25 mm Hg).

For accurate measurement the echo beam must be aligned as parallel as possible with the main pulmonary artery trunk or in the direction of the flow seen on color Doppler. If the beam is not parallel, underestimation of

Fig. 167-3 Doppler interrogation in a dog with severe pulmonic stenosis. Pulmonic insufficiency (arrow) is also seen.

the severity of stenosis occurs. If tricuspid insufficiency is present, the same Doppler technique can be used to calculate the pressure difference between the right atrium and right ventricle by measuring the peak velocity of the tricuspid insufficiency jet. RV pressure then can be estimated by adding the pressure gradient to the estimated right atrial pressure. Echocardiographic-derived Doppler estimates of systolic pressure have shown very good correlation with invasive pressure measurements when done simultaneously.

Color Doppler imaging demonstrates an abnormal flow pattern originating at the stenotic valve. Normal flow is coded as red or blue, depending on whether it is directed toward or away from the transducer, respectively. High-velocity, turbulent flow through a stenotic valve appears as a mosaic of color or a turbulence encoding (often yellow or green). Visualization of the jet by color Doppler also facilitates optimal alignment of the Doppler beam, allowing for more accurate pressure gradient estimations. Color Doppler may also identify complicating factors,

including atrial or ventricular shunts, tricuspid regurgitation, or dynamic obstruction in the *left* ventricular outlet related to altered ventricular geometry.

Classification of Disease Severity

In patients with relatively normal cardiac output, grading of lesion severity is based on RV pressure and valve gradient. The tighter the stenosis, the higher the RV pressure and valve gradient. Most cardiologists use the following Doppler-derived peak transvalvular pulmonary valve gradients to classify the severity of the stenosis:

- Mild: Doppler gradient up to 40 to 50 mm Hg
- Moderate: Doppler gradient between 40 and 80 (to 100) mm Hg
- Severe: Doppler gradient greater than 80 (to 100) mm Hg

TREATMENT

Firm guidelines for deciding which animals need to be treated have not been developed. In pediatric cardiology most interventionalists agree that treatment should be performed in any child with moderate stenosis or a gradient greater than 40 mm Hg. Most veterinary cardiologists would agree that animals with gradients in the severe range should be treated. The decision as to whether to treat dogs with moderate stenosis is not as clear. Many factors can be taken into consideration when making this decision such as degree of RV hypertrophy, presence of clinical signs, and severity of concurrent tricuspid insufficiency. However, it is my opinion that therapy should always be offered and recommended for any patient with a gradient over 60 mm Hg.

Medical Therapy

Medical therapy is of little benefit unless signs of right-sided congestive heart failure are present. In these cases standard therapy for heart failure is recommended in addition to, not in lieu of, interventional therapy. β -blockers such as atenolol (0.5 to 1 mg/1 kg PO q12h) can be used in attempts to reduce arrhythmias, infundibular gradient, dynamic left ventricular outflow gradient, and syncopal events and to prevent sudden death. β -blockage is variable in terms of benefit and does not overcome the primary lesion.

Therapy

Pulmonary balloon valvuloplasty is the first line of treatment for PS. Valvuloplasty should be performed in any symptomatic patient as soon as PS is diagnosed. Even asymptomatic patients should be treated as soon as possible. Delay in treatment can lead to progression of RV and infundibular hypertrophy, not only making the procedure technically more difficult but also diminishing the immediate response to therapy. In fact, in some patients with significant infundibular hypertrophy, this subvalvular gradient can become acutely more severe following dilation of the stenosed pulmonary valve. This condition,

termed *suicide right ventricle*, occurs immediately following relief of severely stenosed valves. RV pressures dramatically increase as the hypertrophied infundibulum creates subvalvular obstruction that can sometimes become worse than the valvular obstruction. Therapy with intravenous β -blockers (esmolol 0.05 to 0.5 mg/kg slowly IV as a bolus) and volume loading of the right ventricle with intravenous fluid boluses can improve or alleviate this subvalvular obstruction.

As described previously, subvalvular PS in English bulldogs and boxers can be caused by an anomalous left coronary artery. Recognition of this abnormality on echocardiographic or angiographic studies is imperative because balloon dilation in these patients has been reported to cause rupture of the artery and sudden death of the patient. Balloon dilation in these patients is risky, and surgical conduit placement around the stenosis may be the only alternative. Less aggressive balloon dilation may also be performed in dogs with severe stenosis, right-sided congestive heart failure, or other clinical signs; but this procedure carries the same risks.

Interventional catheter-based procedures should only be performed by veterinarians with advanced training in these techniques. The technique for pulmonary balloon valvuloplasty involves placement of a dilation balloon across the stenosed valve. The entire procedure is performed under fluoroscopic guidance. A balloon that is 1.2 to 1.5 times the measured pulmonary annulus (from either echocardiographic or angiographic studies) is most often used. The balloon is placed from either a jugular or femoral vein using a vascular cutdown or percutaneous approach. Once the balloon is positioned across the stenosed valve, it is inflated with fluid under pressure to stretch or break open the valve. The balloon is kept inflated for only a few seconds. Multiple inflation-deflations are performed until a satisfactory degree of dilation is achieved. When the balloon is inflated initially, there is an indentation in the balloon at the region of the stenotic valve. This is called a *waist*. Successful dilation is achieved with visualization of a loss of this waist during inflation. On successful balloon dilation RV pressures and valve gradients decrease. This decrease following dilation can be detected immediately with intracardiac pressure monitoring. In pediatric cardiology a good outcome is defined as a residual Doppler gradient of 35 mm Hg or less. In veterinary cardiology reduction of the gradient to 50% of the original value is generally thought of as successful. Complete resolution of gradients across the valve in these patients is not possible because most valves are somewhat dysplastic and always cause at least some obstruction to flow. Accurate assessment of results requires evaluation of Doppler-derived gradients or gradients indexed to stroke volume in the ensuing weeks to months after catheterization.

Serious complications that can occur during this procedure are rare but include cardiac perforation causing pericardial effusion and tamponade, rupture of the pulmonary artery, suicide right ventricle, and fatal arrhythmias. Minor complications that occur with more frequency include damage to the tricuspid valve, creation of a right bundle branch block, temporary arrhythmias, and hemorrhage from vascular access sites. These latter complications are rarely clinically important, and most patients are discharged from the hospital the following day.

Follow Up

Short Term

Intracardiac pressure measurements are usually taken immediately before and after balloon dilation to guide therapeutic decisions. If the gradient or RV pressure has not decreased satisfactorily and there is not dynamic obstruction to explain the gradient, a larger balloon may be placed, and the procedure repeated.

Echocardiographic studies are performed the day following the procedure. Repeat of all measurements are made, with specific attention to valvular gradients and amount of pulmonary insufficiency and tricuspid insufficiency. Pulmonary insufficiency is virtually always increased following balloon valvuloplasty but is well tolerated by the right ventricle. However, tricuspid insufficiency is usually diminished because of the drop in the RV pressure created by the valvuloplasty procedure. Gradients measured the day after the procedure may not show as dramatic a drop as those measured immediately following the procedure. Pulmonary valve leaflets become swollen and edematous following balloon dilation and may temporarily increase the measured gradient until the swelling has subsided. Furthermore, stroke volume greatly influences gradients and is typically lower in dogs under general anesthesia.

Long Term

Long-term follow-up studies in pediatric cardiology show excellent results. Several recent veterinary studies have also shown that pulmonary balloon valvuloplasty significantly reduces valvular gradients and clinical signs in dogs with PS. Recheck evaluations are typically performed 3 and 6 months after the valvuloplasty procedure

and then annually. Gradients can continue to decline in the first 3 to 6 months and possibly even longer as resolution of valve edema and regression of RV/infundibular hypertrophy occurs. Therefore determination of whether a valvuloplasty procedure has been successful should not be judged until several months following the procedure. Some cardiologists continue β -blockade in dogs with residual hypertrophy and dynamic RV outflow obstruction.

Subaortic Stenosis

R. LEE PYLE, *Blacksburg, Virginia*

JONATHAN A. ABBOTT, *Blacksburg, Virginia*

Subaortic stenosis (SAS) resulting from a fibrous lesion that partially or completely encircles the subvalvular outflow tract is one of the most common cardiac malformations in the dog. Planned breeding experiments confirmed that SAS in Newfoundlands is heritable (Pyle, Patterson, and Chacko, 1976); and based on observed breed predispositions, it is likely that canine SAS generally has a genetic basis. The severity of the stenosis and associated clinical consequences vary widely. Dogs with severe SAS are at high risk of complications, including sudden death; but mild SAS seldom is responsible for morbidity or mortality.

The diagnosis of moderate or severe SAS generally is straightforward, although antemortem identification of mildly affected individuals can be difficult. SAS has been treated both medically with catheter-based methods and surgically, but evidence of efficacy for any specific management strategy currently is lacking.

ETIOLOGY

Studies performed during the 1970s confirmed that SAS in Newfoundlands has a genetic basis (Pyle, Patterson, and Chacko, 1976). The mode of inheritance was not completely defined, but the results of planned breeding experiments suggest that SAS is either a polygenic trait or an autosomal-dominant trait that is subject to modification by other genes or environmental factors. Because inheritance of SAS is not explained by simple Mendelian genetics, dogs with mild SAS may have severely affected offspring. As a result, detection of mild SAS is important despite the fact that mild outflow tract obstruction usually does not have clinical consequences.

SAS is observed most often in large- and giant-breed dogs. The German shepherd, boxer, golden retriever, Newfoundland, and rottweiler are all predisposed to the development of SAS. Mongrels are less likely to develop SAS than are purebred dogs, further suggesting that canine SAS is a genetic disorder. In recent years SAS has been identified in *many* other breeds.

PATHOLOGY

The subvalvular lesion is fibrous or fibrocartilaginous. In the mildest form of SAS the lesion consists of subvalvular nodules, and these cases may be clinically silent. More severe forms of SAS result in outflow tract obstruction caused by a ridge that partially or completely encircles the subvalvular left ventricular outflow tract (LVOT) (Fig. 168-1). The most

severe forms consist of plaque or tunnel lesions that involve a large area of the LVOT (Fig. 168-2).

In pathologic studies of SAS in the Newfoundland, subvalvular lesions were detected only in pups that were older than 3 weeks. Based on this finding, SAS is not strictly congenital but rather develops early in life. This observation also has been made in humans. It has been speculated that the lesion arises because morphologic abnormalities in the LVOT increase shear stress and induce proliferation of cells in the LVOT (Freedom et al., 2005). In the dog the obstruction may progress for the first 12 months of life; this has important implications for diagnostic screening, genetic counseling, and patient prognosis.

PATHOPHYSIOLOGY

Outflow tract stenosis impedes ventricular ejection. To maintain normal perfusion pressure distal to the stenosis, the left ventricle must generate supraphysiologic systolic pressures. As a result there is a systolic pressure difference, or gradient, across the obstruction. This pressure gradient can be measured by selective catheterization but more often is estimated from Doppler echocardiographic studies. The pressure load that results from high resistance to ventricular ejection is a stimulus for the development of left ventricular concentric hypertrophy. Concentric hypertrophy is an increase in myocardial mass that is associated with a normal or reduced diastolic chamber dimension. As a result the ventricular walls are thick relative to lumen size. SAS is associated with arteriosclerotic lesions of the intramural coronary arteries. Abnormally narrow coronary vessels, large myocardial mass, and left ventricular systolic hypertension contribute to the development of myocardial ischemia, which is likely the predisposition for the ventricular arrhythmias that sometimes complicate SAS. Although a chronic left ventricular pressure load can result in the development of systolic myocardial dysfunction, this is relatively uncommon in dogs with SAS unless it is severe and chronic. Diastolic dysfunction can be shown by advanced Doppler studies.

In general dogs with mild or moderately severe obstructions are at low risk of premature death. However, a few patients in this category develop complications of longstanding SAS, including infective endocarditis and congestive heart failure. Dogs with severe obstruction are at much greater risk for serious sequelae. Sudden unexpected death, presumably the result of lethal ventricular tachyarrhythmia, occurs in the first 2 to 3 years of life in a substantive number of cases (Kienle, Thomas, and Pion, 1994).

Fig. 168-1 Echocardiogram from an 11-month-old golden retriever with exercise intolerance and a grade IV/VI systolic murmur heard best in the left 4th to 5th intercostal spaces. The sector scan and the insert of the aortic valve (AV) were recorded from the right parasternal short-axis view. Note that the complete subaortic ring (arrows), which was immediately below the aortic valve (8 mm), encompasses considerably less area than the aortic valve. This stenosis resulted in a peak systolic pressure gradient of 150 mm Hg as measured by continuous wave Doppler. LA, Left atrium.

DIAGNOSTIC APPROACH

There are two distinct goals in the evaluation of patients suspected to have SAS: (1) identification and characterization of LVOT obstruction to provide prognostic information and guide therapy, and (2) elimination of affected dogs from the breeding population.

At the time of initial diagnosis most patients with SAS are asymptomatic; this is true regardless of the severity of obstruction. The history in mildly or moderately affected dogs is unremarkable and reflects normal behavior and activity. In severely affected dogs exercise intolerance, weakness, and syncope are noted occasionally. When left heart failure is present, signs can include coughing, dyspnea, and tachypnea.

In mildly or moderately affected dogs, a grade 1-4/6 systolic murmur can be heard best in the left fourth to fifth intercostal spaces at the costochondral junction. Severely affected dogs usually have a grade 4-6/6 systolic murmur often with a precordial thrill. Typically the murmur radiates widely and can be heard over the right lower hemithorax and in the thoracic inlet. In patients with severe SAS the arterial pulse is usually late rising and weak.

The diagnostic value of electrocardiography and radiography in the evaluation of SAS is low. Dogs with mild or moderate SAS usually have a normal electrocardiogram, but evidence of left ventricular hypertrophy may be detected in severely affected patients. Ventricular arrhythmias, including ventricular premature beats and ventricular tachycardia, are sometimes recorded. Depression of the ST segment suggests myocardial ischemia and is most evident on exercise or ambulatory electrocardiograms.

Fig. 168-2 Necropsy specimen from an Irish wolfhound with a plaque/tunnel-type subaortic stenosis (SAS) lesion. This dog developed bacterial endocarditis at 7 months from a urinary tract infection. The effects of the high-velocity SAS jet on the aortic valve leaflets predisposed to the infection. The arrows and the metric define the plaque SAS lesion in the left ventricular out-flow tract. The three aortic valve leaflets (arrowheads) were thickened, nodular, and rigid. The center of each leaflet had a 2-mm perforation presumably caused by the erosive action of the bacteria. Echocardiographic studies revealed SAS, severe aortic regurgitation, a dilated left ventricle, mild mitral regurgitation, and extensive disease of the aortic valve caused by endocarditis and extension of the plaque material into the base of the aortic valve leaflets. The dog died suddenly at 27 months of age after long-term therapy for endocarditis. AO, Ascending aorta.

Thoracic radiographs are of limited value in identifying SAS. Left ventricular enlargement is usually not evident; however, poststenotic dilatation of the ascending aorta may be recognized in severely affected patients.

ECHOCARDIOGRAPHY

SAS is an echocardiographic diagnosis. Except in cases for which balloon dilation is considered, echocardiography essentially has eliminated the need for cardiac catheterization for this disease. The subaortic lesion can often be visualized in severely affected dogs (see Fig. 168-1). Although the relationship between severity of obstruction and degree of hypertrophy is inconsistent, there is often echocardiographic evidence of concentric left ventricular hypertrophy in patients in which the lesion is visible. Left ventricular systolic performance evaluated by fractional shortening or ejection fraction is normal to hyperdynamic in most dogs. A few patients, typically those with long-standing SAS, develop ventricular dilation and evidence of systolic myocardial dysfunction.

Doppler echocardiography is required to confirm the presence of LVOT obstruction and provide an indirect assessment of stenosis severity. When a discrete obstruction is present, the resulting pressure gradient is associated with abrupt flow acceleration within the LVOT. The maximal instantaneous systolic pressure gradient (ΔP = mm Hg) across the stenosis is determined by the simplified Bernoulli equation

$$\Delta P = V^2 \times 4$$

where ΔP is the pressure gradient and V is the peak velocity (meters/second) across the LVOT. A gradient of 40 mm Hg or less reflects mild disease, and a gradient greater than 80 mm Hg is considered severe disease by most (Kienle, Thomas, and Pion, 1994). It is important to recognize that the pressure gradient across the LVOT is flow dependent, meaning that the gradient depends not only on the cross-sectional area of the stenotic orifice but also on stroke volume (Bonagura, 2001). Sympathetic activation associated with restraint and disorders such as aortic valve regurgitation or patent ductus arteriosus increase forward stroke volume and therefore peak aortic velocity. On the other hand, factors that decrease stroke volume and peak velocity include myocardial dysfunction, sedatives, anesthetics, and mitral regurgitation. The flow dependence of peak aortic velocity limits the usefulness of pressure gradient as a single index of stenosis severity.

The accuracy of the Doppler velocity estimate is critically dependent on the angle between the ultrasound beam and the direction of blood flow. Peak aortic velocities can be obtained using a caudal left parasternal or subxiphoid transducer site (Lehmkuhl and Bonagura, 1995). In most dogs the subxiphoid site provides superior alignment with the LVOT and is more accurate.

Other echocardiographic abnormalities occasionally are associated with SAS. The caudal border of the LVOT is bounded by the anterior mitral valve leaflet. Severe SAS involves the base of the anterior mitral leaflet, which probably explains the association of mitral dysplasia and SAS. In a few cases dynamic outflow tract obstruction caused by systolic anterior motion of the mitral valve complicates the fixed obstruction that results from the subaortic lesion. Occasionally mitral valve dysplasia creates marked LVOT obstruction and should be included in the differential diagnosis of left ventricular concentric hypertrophy.

IDENTIFYING MILD DISEASE

The diagnosis of moderate or severe SAS is not difficult. Typically imaging (2D) echocardiography reveals distinct abnormalities, and the diagnosis is confirmed and refined by Doppler studies. Identification of mildly affected dogs is a challenge and a source of considerable controversy. Auscultation is the initial method of screening for congenital heart disease. It is important to realize that a few dogs with mild disease are clinically normal in all respects, including auscultation (Pyle, Patterson, and Chacko, 1976). Consequently it is probable that dogs with mild disease occasionally are classified as free of congenital heart disease. In our practice dogs that do not have a murmur are not subject to further diagnostic

investigation. Because SAS may progress during the first 12 months of life, we frequently screen young pups of predisposed breeds but withhold a final determination until the animal is at least 1 year of age.

The prevalence of low-intensity ejection-type murmurs in dogs predisposed to SAS is high, and it seems unlikely that all of these murmurs are associated with LVOT pathology. Sometimes the murmur is intermittent and heard only after long diastolic intervals or alternatively when heart rate increases. Although we do not routinely do so, some examiners perform auscultation when the dog is at rest and again after exercise. The increase in stroke volume associated with exercise may provoke a murmur in patients with mild SAS and increase the sensitivity of auscultation as means to detect disease. However, this practice also amplifies many functional or innocent murmurs. Postexercise auscultation is made difficult by the increase in respiratory sounds. Furthermore, the prevalence of transient, exercise-induced functional murmurs in normal dogs is not known.

Thorough echocardiographic evaluation of dogs with congenital heart disease sometimes requires sedation. When necessary, we use buprenorphine (0.007 mg/kg intravenously [IV]) and acepromazine (0.03 mg/kg IV) because this sedative combination has minimal effects on Doppler variables. When mild SAS is suspected, we avoid sedation to eliminate the cardiodepressive effect of chemical restraint. There is more variability in the level of anxiety experienced by patients that are not sedated, and this needs to be considered when evaluating dogs for SAS.

In patients with mild SAS the outflow tract lesions are small and often impossible to detect using two-dimensional echocardiography. Detection of a velocity step-up during pulsed-wave Doppler interrogation of the LVOT is a characteristic feature of discrete obstruction. In cases in which mild SAS is suspected, this echocardiographic characteristic is seldom distinct, and it must be recognized that small pressure gradients and gradual flow acceleration are evident in normal individuals. Furthermore, the magnitude of acceleration in healthy dogs has not been defined. The detection of a systolic flow disturbance within the proximal aorta is another echocardiographic characteristic of subvalvular obstruction. Unfortunately it is difficult to define Doppler characteristics of disturbed (turbulent) flow objectively. Aortic valve incompetence (AI) is uncommon in normal dogs but is often associated with subaortic obstruction. The cause of AI in patients with SAS is likely multifactorial, but damage to the ventricular surface of the aortic valve leaflets from the high-velocity jet is probably important.

Because it is objective and easily quantified, peak aortic velocity generally is considered to be the primary diagnostic criterion for SAS. Although high velocities can be recorded in the absence of obstruction, the diagnosis of obstruction generally is not tenable when peak velocity is normal. Aortic velocities in most healthy dogs without systolic murmurs are less than 1.9 m/second, and the average velocity is close to 1.3 m/second. Nevertheless, there is an avid debate about the velocity that distinguishes normal dogs from dogs with mild SAS. Because peak velocity is determined by stroke volume and outflow tract geometry, there is a physical basis

for high aortic velocities that occur in the absence of obstruction. For example, peak aortic velocities exceeding 2.25 m/second are commonly recorded when healthy dogs are subject to dobutamine infusion. However, the ventricle does not have a normal appearance when these high velocities are recorded. Instead the ventricle is hyperdynamic, and fractional shortening typically is greater than 45%. Similarly, when high aortic velocities are recorded from dogs with patent ductus arteriosus, the ventricle is dilated; and, provided fractional shortening is normal, this is indirect evidence of a large stroke volume. It seems unlikely that an echocardiographically normal ventricle that empties into an aorta of normal diameter will generate velocities that exceed 2.25 m/second. Although some breeds such as the boxer may have a relatively smaller aorta that might predispose to high flow rates, it is very unlikely that there is a *single* minimum velocity that identifies outflow tract obstruction in all cases. However, in our opinion under most circumstances a velocity greater than 2.25 m/second is suggestive of SAS. A velocity that is less than 2.25 m/second but greater than 1.9 m/second is difficult to interpret and represents an equivocal finding in our laboratory. Although Doppler studies do not overestimate velocity, sinus arrhythmia can cause marked variability in aortic velocities; therefore the use of an average of three to five consecutive velocities is recommended.

It should be recognized that studies of healthy dogs from which reference intervals have been derived excluded dogs with murmurs and have recruited dogs of different breeds. With respect to the possibility of a breed effect, boxers deserve mention. In a study of healthy boxers more than 50% had soft basilar ejection murmurs (Kopitz et al., 2003), and the boxers that had murmurs had higher aortic velocities than boxers that did not. The cause of these murmurs was not identified definitively, and it was speculated that an exaggerated response to sympathetic tone or an anatomic variant in the LVOT such as generalized aortic hypoplasia might explain the findings. Very possibly ejection murmurs heard in boxers result from two distinct causes: some are caused by SAS, and others are physiologic murmurs that relate to a breed-specific variation in outflow tract anatomy.

We believe that peak velocity is only a single variable in a dynamic system. Indeed some cases cannot be resolved as to cardiac status because objective, irrefutable evidence of SAS is lacking. Exclusion of a large proportion of the breeding population based on a single diagnosis may have a negative effect on the population genotype. Because of this, in equivocal cases the murmur and results of echocardiographic examination are documented, and the breeder is informed of the potential genetic implications of the findings. Breeding of animals in this equivocal category is not necessarily discouraged for dogs with otherwise strong characteristics, but careful evaluation of progeny is recommended. Only through breeding studies and/or necropsy evaluation does the real status of some dogs become known. Currently there is no available genetic test to identify affected dogs or carriers of SAS.

TREATMENT

Dogs with mild or moderate SAS typically are not treated in our practice. Generally these animals have few complications from their disease. Severely affected dogs do not fare as well and commonly die suddenly and unexpectedly presumably as a result of a lethal ventricular arrhythmia (Kienle, Thomas, and Pion, 1994). Unfortunately the treatment options are limited and of questionable value. A recent report (Meurs, Lehmkuhl, and Bonagura, 2005) summarized the results of transcatheter balloon dilation in dogs with severe SAS. Although short-term reduction of the peak systolic pressure gradient was found, there was no long-term benefit in survival times when compared to a group of dogs receiving atenolol; median survival in both groups was about 4 years. The weakness in this study was a lack of an untreated control group, although the median survival was longer than untreated dogs reported by Kienle, Thomas, and Pion (1994). Until a control group is studied, it is not possible to know with certainty whether balloon valvuloplasty or β -blocker therapy offers severely affected animals any benefit. The balloon dilation results are not surprising, considering the location of the SAS lesion and the nature of the stenotic lesion (see Figs. 168-1 and 168-2). In humans it has been stated that balloon dilation is rarely justified as a mode of therapy (Freedom et al., 2005).

When considering therapy with atenolol, we evaluate clinical signs, electrocardiographic findings, and echocardiographic results with particular emphasis on pressure gradient. Although we recognize the lack of data for the use of a beta blocker in this disease, we often recommend atenolol (0.5 to 1 mg/kg PO q12h) for severely affected animals. The presumed beneficial effect of β -blockade relates to the decrease in myocardial oxygen demand that is associated with the negative inotropic and chronotropic effects. Blunting of the chronotropic response to exercise may improve myocardial perfusion because coronary flow in patients with severe SAS occurs primarily during diastole (Pyle et al., 1973). In addition, a phenomenon of reflex-mediated bradycardia and hypotension has been described in people with aortic stenosis. It is possible that the same pathophysiologic mechanism explains syncopal episodes in dogs with SAS. Since adrenergic activation is believed to be the stimulus that initiates the reflex, atenolol or other β -blockers may be helpful.

It is possible that the effects of β -blockade reduce the frequency and potentially fatal outcome of arrhythmias in SAS; however, evidence to support this contention is lacking. In the absence of controlled studies or a precedent in pediatric medicine, it is also appropriate to consider the possibility that atenolol might harm patients with SAS. β -Blocker therapy could be detrimental because stroke volume in patients with severe SAS can be considered "fixed" by the structural impediment to ejection. The negative inotropic effect of β -blockers might limit the ability to generate the high ventricular pressures that are required to maintain stroke volume and coronary perfusion during exercise. Exercise restriction likely accomplishes many of the objectives of β -blockade; therefore exercise restriction is discussed with owners of dogs with severe SAS.

Other forms of medical therapy are seldom indicated. Medical management of congestive heart failure or atrial fibrillation is occasionally necessary for long-surviving patients with SAS. In these cases diuretic therapy is indicated, and digoxin is used to slow ventricular response rate when the presentation is complicated by atrial fibrillation. Historically vasodilators were believed to be contraindicated in patients with severe, fixed outflow tract obstruction. However, recent clinical data from humans with heart failure caused by aortic stenosis suggest that there may be a role for vasodilation when there is concurrent aortic stenosis and systolic myocardial dysfunction. Based on this, ACE inhibitors can be considered as adjunctive therapy for canine patients with SAS, heart failure, and echocardiographically confirmed myocardial dysfunction.

Infective endocarditis is a serious complication of SAS (see Fig. 168-2). Because many SAS dogs have abnormal aortic valve leaflets, antibiotics should be used before elective surgical or dental procedures that cause bacteremia.

Results of surgical correction have not been encouraging (Orton et al., 2000). Twenty-two dogs with severe SAS were treated with an open surgical approach; another 22 dogs were not treated with surgery. Intermediate-term outcome did not show a positive survival benefit; however, there was a decrease in systolic pressure gradient and a possible improvement in exercise tolerance. The reason this invasive procedure did not significantly improve the outcome is unknown, but the findings suggest the possibility that the

substrate for sudden death, perhaps myocardial fibrosis, is established early in the course of the disease. As a result of this study, we do not recommend surgical correction.

Tricuspid Valve Dysplasia

DARCY B. ADIN, *Rochester, New York*

Tricuspid valve dysplasia is congenital malformation of the right atrioventricular valve apparatus and is thought to be caused by abnormal tissue undermining the right ventricle during embryogenesis (Garson et al., 1998). A variety of abnormalities are encountered, including thickened, shortened, or elongated leaflets; shortened or absent chordae tendineae; and abnormal papillary musculature. The major consequence of a malformed tricuspid valve is systolic regurgitation of blood into the right atrium, resulting in volume overload of the right heart. This tricuspid valve regurgitation can lead to right-sided congestive heart failure and atrial arrhythmias.

Tricuspid valve stenosis occasionally may be a feature of the disease and is characterized by impaired diastolic opening as a result of thickened and fused leaflets. Tricuspid valve stenosis induces atrial hypertrophy and enlargement and can also lead to congestive signs and arrhythmias. Cyanosis and polycythemia may occur in cases of concurrent atrial septal defect or patent foramen ovale.

Ebstein's anomaly is a related congenital defect whereby the origins of the tricuspid leaflets are apically displaced into the right ventricle. It may or may not be associated with leaflet dysplasia. Ebstein's anomaly has only rarely been documented in the veterinary literature (Chetboul et al., 2004; Takemura et al., 2003). Other congenital anomalies may be observed concurrently with tricuspid dysplasia, including mitral dysplasia, septal defects, pulmonary stenosis, and patent ductus arteriosus (Liu and Tilley, 1976). The foramen ovale may remain patent as a result of elevated right atrial pressure and dilation.

SIGNALMENT

Tricuspid dysplasia is a relatively uncommon defect, accounting for approximately 7% of canine congenital cardiac defects in retrospective studies (Baumgartner and Glaus, 2003; Tidholm, 1997). A variety of large-breed dogs have been reported, including Labrador retrievers, boxers, golden retrievers, Irish setters, Great Danes, and German shepherds (Andelfinger et al., 2003; Chetboul et al., 2004; Kornreich and Moïse, 1997; Liu and Tilley, 1976). The disease has been shown to be inherited in the Labrador retriever in an autosomal-dominant manner with incomplete penetrance and has been mapped to chromosome 9 in this breed (Andelfinger et al., 2003).

Tricuspid dysplasia is diagnosed less frequently in cats. It has been reported most commonly in the domestic shorthair cat but also in chartreux and Siamese cats (Chetboul et al., 2004; Kornreich and Moïse, 1997; Liu and Tilley, 1976).

DIAGNOSIS

Clinical Findings

Dogs and cats with tricuspid valve dysplasia may be clinically well with a heart murmur or presented for right-sided congestive heart failure. Although most animals are evaluated at a young age, it is not uncommon to make the diagnosis in an older animal at the time that clinical signs develop.

The hallmark physical examination feature for animals with tricuspid dysplasia is a right apical systolic murmur. The intensity of the murmur can vary from very soft to very loud with a precordial thrill and depends on the amount of regurgitation and the velocity of flow across the valve. Considering the latter factor, murmur intensity may not always reflect the severity of the disease. For example, a dog with a large tricuspid orifice resulting from severe malformation and volume overload of the right heart may have nearly laminar regurgitant flow because of pressure equilibration between the right atrium and right ventricle. Some of these dogs have a very soft murmur.

Dogs that are severely affected may be presented in right-sided congestive heart failure with jugular venous distention or pulsation, hepatomegaly, and ascites. Femoral arterial pulse quality is expected to be normal unless the disease is very severe. Mucous membrane color is normal unless a coexistent right-to-left shunt is present. Animals with right-sided congestive heart failure often have poor body condition.

Electrocardiography

The most common electrocardiographic finding in animals with tricuspid valve dysplasia is a splintered QRS complex, with as many as two thirds of dogs and cats showing this abnormality (Kornreich and Moïse, 1997). Splintering describes an Rr', RR', rR', or rr' morphology of the QRS complex (Fig. 169-1). The underlying mechanism for splintering is not known; however, several possibilities include ventricular fibrosis resulting in altered conduction, right bundle branch conduction disturbances, and accessory pathway conduction.

A right heart enlargement pattern may also be seen in approximately one third of dogs and one half of cats with tricuspid dysplasia (tall and sometimes wide P waves and deep S waves in leads I, II, and III and aVF with a right axis deviation) (Kornreich and Moïse, 1997). The use of precordial leads in dogs increases the sensitivity of the electrocardiogram to these changes.

Right atrial enlargement predisposes dogs and cats to atrial arrhythmias, including atrial premature complexes,

Fig. 169-1 Electrocardiogram from a dog with tricuspid dysplasia. Note the splintered QRS complex (rR'). The rhythm is atrial fibrillation.

atrial tachycardia, atrial flutter, and atrial fibrillation (see Fig. 169-1). The development of atrial tachyarrhythmias may decompensate a patient and initiate congestive symptoms because of the ensuing decrease in cardiac output and increase in atrial pressure.

Radiography

Right heart enlargement can be detected with thoracic radiography and can be profound in animals with severe tricuspid valve dysplasia (Fig. 169-2). The massive cardiomegaly in some cases may lead to differential diagnoses of dilated cardiomyopathy and pericardial effusion; however, physical examination and echocardiographic findings are definitive for tricuspid dysplasia. The right atrium is often the predominant chamber noted on thoracic radiographs, occupying the majority of the cardiac silhouette. The apex may be shifted dorsally on the lateral view and to the left and caudally on the ventrodorsal projection because of right heart enlargement. Notably the main pulmonary artery is normal, and the pulmonary vasculature may be normal or suggest decreased perfusion. Dogs that are in congestive failure with ascites have radiographic evidence of caudal vena caval enlargement (greater than the length of the fifth thoracic vertebrae).

Echocardiography

Echocardiography provides the definitive diagnosis for tricuspid valve dysplasia. The septal leaflet of the tricuspid valve often appears tethered to the interventricular septum. The leaflet tips are thickened and often curled. In severe cases it may be possible to identify a coaptation gap whereby the valve leaflets visibly do not meet in systole (Fig. 169-3). The papillary muscles are abnormally

large with direct valve leaflet insertion. When chordae tendineae are present, they are thickened and short. Although both the right ventricle and right atrium are volume overloaded, right atrial enlargement predominates (see Fig. 169-3). The left ventricle is usually markedly volume underloaded. Doppler interrogation shows a large regurgitant jet across the tricuspid valve. The velocity of the tricuspid regurgitation is predictive of normal right ventricular pressure and generally less than 2.8 m/second. Ebstein's anomaly is identified by a marked apical displacement of the tricuspid valve insertions such that a portion of the right ventricle is "atrialized." The determination of apical displacement should be cautious, remembering that the normal insertion point of the tricuspid valve is slightly more apical than the normal insertion point of the mitral valve. In addition, care must be taken not to overinterpret any leaflet tethering that may be present. Ebstein's anomaly can be confirmed by invasively obtaining a ventricular electrogram and an atrial pressure pulse from this atrialized portion of the right ventricle.

When tricuspid stenosis is present, the right ventricle appears small, and the right atrium is enlarged. The resulting pressure overload induces right atrial hypertrophy and dilation. The thickened valve leaflets are usually observed to "dome" in diastole because their opening is restricted. Continuous-wave Doppler shows a delayed pressure gradient decay in early diastole as a result of the obstruction. In addition, the pressure gradient across the tricuspid valve is abnormally elevated and highest in late diastole after atrial contraction.

There is a growing interest among breeders to screen dogs for tricuspid dysplasia; however, there currently is no consensus among cardiologists regarding the optimal method of screening (auscultation only versus echocardiography) or regarding the precise echocardiographic

Fig. 169-2 Lateral (**A**) and ventrodorsal (**B**) radiographs from a dog with severe tricuspid dysplasia. Severe right-sided cardiomegaly is present. The apex is shifted dorsally on the lateral projection and to the left on the ventrodorsal radiograph.

Fig. 169-3 Left apical parasternal echocardiographic image showing a severely enlarged right atrium and right ventricle. The tricuspid valve leaflets are thickened and attach directly to the papillary muscles. The septal leaflet is tethered to the interventricular septum. Based on the electrogram, the image is during systole when the valve leaflets should be closed; this valve has a very large coaptation gap.

criteria for the differentiation between normal and mildly affected dogs.

THERAPY

Medical therapy is instituted once ascites or, less commonly, pleural effusion develops. Diuretics (e.g., furosemide) and

angiotensin-converting enzyme inhibitors (e.g., enalapril) are used to counteract fluid retention; however, it is uncommon for medications to eliminate third spacing of fluids entirely. Periodic manual removal of effusions (e.g., abdominocentesis) is often required despite concurrent diuresis. Because elevated hydrostatic pressure is the driving force for fluid accumulation, there should be no concern about complete evacuation of the peritoneal space as there would be for ascites caused by hypoproteinemia (aside from loss of protein). Excessive diuresis should be avoided, especially in cases in which low output signs are present (e.g., cool extremities, poor arterial pulses). A reduced sodium diet may help to control congestion; however, adequate nutritional intake is more important than a specific diet because many of these patients become cachectic with disease progression. The use of pimobendan can be considered, but it is not labeled for (or studied in) this disease.

Atrial tachyarrhythmias should be controlled since their development can further compromise a patient that is in or near congestive heart failure. Digoxin is used to slow the ventricular response rate in atrial fibrillation and provides some positive inotropic action; however, it often is inadequate as the sole agent. Diltiazem may be added to digoxin for heart rate control with atrial fibrillation and can be used for the treatment of atrial tachycardia.

Balloon valvuloplasty has been reported twice for the successful treatment of tricuspid stenosis (Brown and Thomas, 1995; Kunze et al., 2002). Surgical replacement of the tricuspid valve has been attempted in a limited number of cases with poor outcomes.

PROGNOSIS

The prognosis depends on the severity of the malformation and the resultant tricuspid regurgitation. Dogs with mild tricuspid valve dysplasia may have normal life spans. Most dogs with severe tricuspid valve dysplasia deteriorate within the first few years of life; however, occasionally congestive heart failure may not occur until later in life, and some dogs survive longer than 6 years even with severe disease.

CHAPTER 170

Mitral Valve Dysplasia

BARRET J. BULMER, *Corvallis, Oregon*

Appropriate opening and closing of the mitral valve allows unimpeded left ventricular filling and prevents valvular regurgitation. These functions depend on the integrated activity of all anatomic components of the mitral valve apparatus. Disruption or malformation of any of these components, including the mitral leaflets, the chordae tendineae, the mitral annulus, the left atrial wall, the papillary muscles, or the left ventricular wall may produce valvular dysfunction. Although acquired degenerative valve disease is the most common cause of mitral valve dysfunction in dogs, it should be recognized that mitral valve dysplasia (MVD) is a common form of congenital heart disease in both dogs and cats. Currently MVD may have surpassed ventricular septal defect as the most common congenital anomaly in cats. Alterations in cases of MVD include annular enlargement; short, thick leaflets with an occasional cleft; short and stout or long and thin chordae tendineae; upward malposition of atrophic or hypertrophic papillary muscles; and insertion of one papillary muscle directly into one or both leaflets (Liu and Tilley, 1975). Animals that

appear to be overrepresented include cats of all breeds, Great Danes, German shepherds, bull terriers, golden retrievers, Newfoundlands, dalmatians, and mastiffs (Oyama et al., 2005).

PATHOPHYSIOLOGY

The pathophysiologic consequences of MVD relate to: (1) systolic regurgitation of blood from the left ventricle into the left atrium; (2) impaired left ventricular diastolic filling across a stenotic mitral valve; or (3) obstruction to left ventricular ejection via inappropriate, systolic displacement of the mitral valve into the left ventricular outflow tract. More than one functional disturbance can occur. Similar to acquired degenerative mitral valve disease, congenital insufficiency of the mitral valve produces volume overload of the left atrium and left ventricle. The two primary determinants of the volume of insufficiency are the regurgitant orifice area (ROA) and the left ventricular-to-left atrial pressure gradient. Therefore animals with a large ROA and those that must generate greater left

ventricular pressures (e.g., MVD complicated by subaortic stenosis) suffer greater hemodynamic consequences compared to animals with small leaks and unimpeded left ventricular ejection. As the left atrial, pulmonary venous, and pulmonary capillary pressures rise secondary to the volume overload, left-sided heart failure develops with accumulation of fluid within the pulmonary interstitium and alveoli.

If the valvular dysfunction is manifested primarily as stenosis, it produces a different range of pathophysiologic consequences. Lesions that restrict pulmonary venous return and left atrial emptying, including mitral stenosis, supraventricular mitral stenosis, and cor triatriatum sinister, are accompanied by elevated left atrial and pulmonary venous pressures. The severity of this pressure increase depends on resistance of the stenotic valve and the volume of transmitral flow, which increases during exercise. In the initial stages of the disease the increased pressure maintains an adequate gradient for left ventricular filling. This elevated pressure gradient contributes to left atrial enlargement and hypertrophy, pulmonary venous congestion, and pulmonary edema because of increased pulmonary capillary hydrostatic pressure. The chronic hypoxia associated with lack of alveolar ventilation may produce reactive pulmonary arterial vasoconstriction in an attempt to diminish ventilation/perfusion mismatch. Ultimately right ventricular dysfunction and right-sided heart failure may develop from the pressure overload associated with long-standing pulmonary hypertension.

The third alteration that may accompany MVD is systolic displacement of the anterior mitral valve leaflet, a chordae tendineae, or papillary muscle into the left ventricular outflow tract. Although systolic anterior motion (SAM) or dynamic left ventricular outflow tract obstruction is most frequently associated with hypertrophic cardiomyopathy, it may also stem from mitral dysplasia independent of septal hypertrophy. Several mechanisms have been hypothesized for this association, including (1) a decrease in the ability of the papillary muscles to restrain the valve posteriorly; and (2) an interposition of the leaflets anteriorly into the outflow stream, which then propels them anteriorly into the outflow tract, and a geometry for mitral valve coaptation that favors SAM (Levine et al., 1995). Consequences of SAM include increases in systolic left ventricular pressure, wall tension, and myocardial work (promoting concentric hypertrophy); increased myocardial oxygen demand; reduced coronary perfusion pressure as aortic diastolic pressure falls and left ventricular diastolic pressure rises; and mitral regurgitation caused by incomplete valve closure (Sherid, 1998).

DIAGNOSIS

History and Physical Examination

Similar to many forms of congenital heart disease, animals with MVD commonly are identified before the development of clinical signs related to abnormal cardiac auscultation during the initial veterinary examination. The absence of clinical signs often continues for a variable period of time until owners begin to recognize evidence of left-sided heart failure (i.e., coughing, tachypnea,

restlessness, and exercise intolerance) predominantly. Uncommonly animals with mitral stenosis may also display evidence of right-sided heart failure (i.e., abdominal distention secondary to ascites formation and tachypnea resulting from pleural effusion). Severe mitral stenosis can be associated with recurrent bouts of flush pulmonary edema or hemoptysis. Less common historical complaints may include syncope, and on occasion animals may die suddenly without a previous history of clinical signs.

The wide range of phenotypic expressions and pathophysiologic consequences for MVD produce a variety of abnormal physical examination findings. No matter if the valve is primarily insufficient or stenotic or displays SAM, the most common auscultatory abnormality is a left apical systolic murmur of mitral valve regurgitation. Careful auscultation in animals with mitral stenosis may identify a left apical, diastolic, rumbling murmur of mitral valve stenosis; whereas patients with SAM often have a left-sided systolic murmur that varies in intensity directly with the heart rate (and sympathetic tone). Additional abnormal cardiac auscultatory findings may include S3 or S4 gallops, a variety of supraventricular or ventricular arrhythmias, and on very rare occasions an audible systolic click or opening snap. Animals with pulmonary edema may have increased bronchovesicular sounds or crackles, whereas those with pleural effusion may have muffled heart and lung sounds. Jugular venous distention or pulsation, a positive hepatojugular reflux, ascites, and/or hepatomegaly may signify the presence of right-sided heart failure.

Electrocardiography

Electrocardiographic alterations that may be identified in animals with MVD include chamber enlargement patterns, arrhythmias, and potentially ST segment alterations. An increased R wave amplitude and prolonged QRS duration may accompany left ventricular enlargement, whereas a prolonged or widened P wave is classically associated with left atrial enlargement (although tall P waves may also be encountered). If significant right ventricular enlargement is present as a result of mitral stenosis and pulmonary hypertension, deep S waves (in leads I, II, aVF, and V₂₋₄), and a right-axis shift in the mean electrical axis may be identified. Small amplitude QRS complexes (<1 mV) may be present in patients with pleural effusion. The most common arrhythmias in animals with MVD are supraventricular (i.e., atrial premature complexes and atrial fibrillation), although ventricular premature complexes also occur. Myocardial ischemia or hypoxia accompanying severe left ventricular concentric hypertrophy or pulmonary hypertension may produce ST segment elevation or depression.

Thoracic Radiography

Radiographic abnormalities in animals with MVD displaying primarily valvular insufficiency include left ventricular and left atrial enlargement. The most consistent radiographic finding in patients with mitral valve stenosis is left atrial enlargement (Lehmkuhl, Ware, and Bonagura, 1994). In cases in which pulmonary hypertension has developed, variable degrees of right ventricular and pulmonary

arterial enlargement may be encountered. The concentric hypertrophy that accompanies animals with MVD and SAM may fail to produce significant chamber enlargement radiographically despite the presence of marked wall thickening. All three forms of MVD may contribute to the development of left-sided heart failure, with pulmonary venous congestion and perihilar interstitial edema ultimately giving way to an alveolar pattern. Hemoptysis creates a dense alveolar pattern. Because MVD is frequently accompanied by other forms of congenital heart disease, the predominant radiographic findings may not be representative of the mitral valve lesion.

Echocardiography

Two-dimensional, M-mode, spectral, and color flow Doppler echocardiography are invaluable in the assessment of animals with MVD. Ultrasonographers experienced with congenital heart disease can quickly ascertain the morphologic features of the dysplastic valve, the principal form (or forms) of valvular dysfunction, the myocardial response to

the malfunctioning valve, and the presence or absence of concurrent cardiac anomalies (Fig. 170-1). Similar to electrocardiograms and radiographs, the echocardiographic findings depend on the primary manifestation and the severity of the valvular dysfunction. Two-dimensional echocardiography enables a detailed evaluation of the location, shape, motion, and attachments of the mitral valve leaflets to their respective chordae tendineae and papillary muscles. Animals with significant mitral insufficiency display eccentric left ventricular hypertrophy, left atrial dilation, and normal-to-hyperdynamic systolic function unless left ventricular dysfunction has developed. Virtually all patients with MVD have evidence of mitral regurgitation on color flow Doppler.

Common echocardiographic findings in patients with mitral stenosis include left atrial enlargement, thickened mitral valve leaflets, diastolic doming of the anterior mitral valve leaflet, and decreased excursion of the tips of the mitral valve. M-mode echocardiography may identify concordant motion of the anterior and posterior mitral valve leaflets, incomplete leaflet separation during

Fig. 170-1 **A**, Elongated and thickened mitral valve with abnormal chordal insertion on the anterior leaflet prevents appropriate closure of this valve. The result is a large volume of mitral insufficiency as evidenced by color Doppler with left atrial (LA) dilation and left ventricular (LV) eccentric hypertrophy in this 6-month-old dog. **B**, Marked left atrial dilation is present in this patient with severe mitral valve stenosis. The dysplastic mitral leaflets are tethered at their coaptation point, preventing the normal diastolic transit of blood from the left atrium into the left ventricle. **C**, This young rottweiler with mitral valve dysplasia displays asymmetrically elongated and displaced papillary muscles that inappropriately contact the chordae tendineae of the anterior mitral valve leaflet and interventricular septum during systole. Moderate-to-severe left ventricular concentric hypertrophy accompanies the dynamic left ventricular outflow tract obstruction because it impairs systolic ejection of blood into the aorta (Ao).

diastole, lack of leaflet closure during mid-diastole, a reduced EF slope, and an increased left atrium-to-aortic ratio (Lehmkuhl, Ware, and Bonagura, 1994). Increased transmitral flow velocities and prolonged pressure half-time are commonly recognized via spectral Doppler.

Animals with MVD and dynamic left ventricular outflow tract obstruction display systolic apposition of the anterior mitral valve leaflet, chordae tendineae, or papillary muscle with the interventricular septum as evidenced via two-dimensional and M-mode echocardiography. Additional echocardiographic findings include variable degrees of concentric left ventricular hypertrophy, partial premature closure of the aortic valve, and high-velocity turbulent flow within the left ventricular outflow tract accompanied by a posterolaterally directed jet of mitral insufficiency. Continuous-wave Doppler interrogation of the left ventricular outflow tract displays a characteristic concave and asymmetrically shaped pattern because the outflow tract obstruction occurs during mid-systole (versus cases of fixed subaortic stenosis). It should be noted that these findings are very similar, if not identical, to those recognized in hypertrophic obstructive cardiomyopathy; and in some cases it is extremely difficult to differentiate these two diseases.

THERAPY

Therapeutic decisions for the management of MVD are based on the form and severity of valvular dysfunction present, the presence or absence of clinical signs, and whether or not concurrent cardiac anomalies are present. Asymptomatic animals with primarily mitral valve insufficiency or mitral stenosis generally warrant client education and careful follow-up without specific medical management. In comparison, β -blockers are commonly administered to animals with systolic anterior motion of the mitral valve, even in the absence of clinical signs, if they have a significant resting or provoked left ventricular outflow tract gradient. Atenolol (0.5 to 1 mg/kg q24h orally [PO]) has been reported to successfully alleviate dynamic left ventricular outflow tract obstruction and left ventricular concentric hypertrophy in dogs with SAM (Connolly and Boswood, 2003). Animals with MVD and congestive heart failure are treated similarly to their counterparts with degenerative mitral valve disease via a regimen of diuretics and angiotensin-converting inhibitors, often with positive inotropic drugs (see Chapter 171). Care must be exercised to avoid overzealous diuretic administration in animals with mitral stenosis because their cardiac output is extremely preload dependent. Antiarrhythmics may be required to manage ventricular premature complexes or slow the ventricular response rate in cases with atrial fibrillation (see Chapter 161). Adequate rate control in animals with mitral stenosis complicated by atrial fibrillation

should be a priority (Meisner et al., 1991). Surgical repair or replacement of the mitral valve using cardiopulmonary bypass has also been reported to palliate or resolve clinical signs in dogs with MVD (White et al., 1995; Griffiths, Orton, and Boone, 2004; Borenstein et al., 2004).

PROGNOSIS

The prognosis for animals with MVD depends on the type and severity of valvular dysfunction and, when required, response to medical therapy. Many animals with mild-to-moderate MVD live for prolonged periods of time free of clinical signs. Following the development of congestive heart failure, the natural history of congenital MVD appears similar to that of dogs with acquired degenerative valve disease. Overall a generally worse prognosis can be given for animals with mitral stenosis, and a generally better prognosis for those with outflow tract obstruction (assuming it and related ventricular hypertrophy are resolved with β -blocker administration) compared to those with valvular insufficiency predominantly. Depending on the morphology of the dysplastic valve and the manifestations of dysfunction, successful surgical repair or replacement of the valve may be curative in selected cases.

Management of Heart Failure in Dogs

BRUCE W. KEENE, *Raleigh, North Carolina*

JOHN D. BONAGURA, *Columbus, Ohio*

The heart is a deceptively complex organ that generates the force by which blood is continuously supplied to perfuse the metabolizing tissues. In all animals with closed circulatory systems (creatures above mollusks phylogenetically), control systems monitor the distention of selected arteries, veins, cardiac chambers, and respiratory organs, as well as some of the chemical properties of the arterial blood supply. These control systems coordinate an array of physiologic and neuroendocrine responses from the heart, blood vessels, kidney, lung, and central nervous system. Together these systems maintain blood volume, arterial pressure, venous pressure, heart rate, cardiac output, and ventilation. These critical variables are further adjusted to levels that support metabolic needs both at rest and during times of stress or exercise.

When the heart fails for any reason, the general outcome is activation of stereotypical responses that attempt to maintain blood pressure (BP) and vital organ perfusion. These compensations are both helpful and maladaptive. Understanding this pathophysiology is central to the therapy of heart failure (HF) and is the initial topic of this chapter.

HF is a syndrome, not a disease. The causes of HF in dogs differ, and the stages of heart disease and HF are often progressive. Appreciating these different causes and stages is helpful in constructing a general framework for managing dogs with heart disease and HF. This subject and the evidence for using specific drugs at various stages of HF is the second focus of this chapter.

Veterinarians have a number of powerful drugs for supporting a failing heart and managing the circulatory, renal, and neurohormonal consequences of HF. The clinical pharmacology of these drugs must be mastered for successful treatment of dogs with HF. Multidrug therapy provides the best outcome for dogs with advanced cardiac disease, and the experienced veterinarian learns to orchestrate these treatments. This chapter includes a brief review of the important clinical pharmacology of cardiac drugs. Finally, insofar as specific treatment recommendations can be advanced, we offer our own approaches to treating HF in dogs in the final portion of this chapter.

CLINICAL PATHOPHYSIOLOGY OF HEART FAILURE

The term *heart failure* describes a pathophysiologic situation in which the heart cannot maintain cardiac output sufficient to meet the perfusion needs of the metabolizing tissues while also maintaining normal venous pressures.

Invariably exercise capacity becomes limited in HF. Whether caused by systolic or diastolic heart dysfunction, decreased cardiac output and arterial BP are pivotal events in the syndrome of HF. In contrast, hemorrhagic or hypovolemic shock is also associated with reduced cardiac output and BP; but in these circumstances venous pressures are low, and the indicated therapy is quite different (see Chapter 1).

In both HF and hypovolemic shock the reduction in cardiac output and resultant decrease in arterial BP (arterial “under-filling”) trigger a cascade of physiologic events coordinated by control systems focused primarily on restoring the arterial pressure toward normal. Activation of these control systems helps maintain basal (resting) BP and blood flow to selected organs within the normal range even in the face of initially reduced cardiac output. These mechanisms include sympathetic stimulation of the heart; vasoconstriction and redistribution of blood flow mediated by sympathetic, renin–angiotensin, vasopressin, and vascular endothelial systems; and sodium and water retention mediated by changes in renal blood flow, aldosterone, vasopressin, and inhibition of natriuretic hormones. These are powerful control systems for restoration of arterial BP. If the cause of decreased cardiac output and BP is reversible and transient, activation of these systems appears to cause no permanent harm, and they promptly return to their basal state once the crisis has passed. Conversely, when chronically activated, the physiologic balance shifts toward vasoconstriction, sodium retention, and mediators of inflammation and tissue growth. Furthermore, the heart itself is remodeled at the expense of structural and functional damage to cardiac muscle, including activation of fetal-gene programs, myocyte apoptosis, and interstitial and replacement fibrosis. These compensatory mechanisms may be so hemodynamically effective that clinical signs of cardiac failure may be absent or evident only with exercise until the time that pulmonary venous pressure increases sufficiently to cause edema or perfusion of skeletal muscles becomes severely limited. These effective but damaging compensations make heart diseases difficult to diagnose until they have caused extensive cardiac remodeling and damage.

Progression of heart disease and pump dysfunction triggers a spiral of increasing dependence on neurohormonal activity to maintain normal arterial BP and flow. Despite the hemodynamic benefits of these compensations (e.g., maintaining normal arterial BP at rest), their chronic activation is maladaptive—a concept central to

the medical management of chronic HF. Clinical signs of congestive heart failure (CHF) are explained in part by chronically elevated venous pressures (causing pulmonary edema, pleural effusion, jugular venous distention, hepatomegaly, and ascites), inadequate tissue perfusion (exercise intolerance, lethargy, and azotemia), and metabolic disturbances (weight loss, insulin resistance, and azotemia). Although hemodynamic changes may explain the acutely life-threatening clinical signs of HF, morbidity and mortality in chronic HF patients appear to be related strongly to the tissue effects of the accentuated neurohormonal and cytokine-mediated compensations that develop in response to the reduced output of the failing heart.

The therapy of acute HF is directed primarily at identifying and “fixing” life-threatening hemodynamic derangements. The chronic therapy of HF is aimed at maintaining hemodynamic gains while modulating and blunting the maladaptive compensatory responses to protect tissues, prolong life, and minimize clinical signs.

CAUSES AND CLASSIFICATIONS OF HEART FAILURE

HF is not a specific disease but a clinical syndrome precipitated by a definable heart disease and characterized by the aforementioned cardiac, hemodynamic, renal, neurohormonal, and cytokine abnormalities. Causes of heart disease can be classified by etiology if known, but many heart diseases are genetic or idiopathic in origin. The classic pathophysiologic description of HF involves ventricular systolic dysfunction, diastolic dysfunction, or hemodynamic (volume or pressure) overload. However, most dogs in HF have elements of each of these categories. In the past HF has also been classified as forward or backward, which is instructive relative to the clinical signs observed in patients. Forward failure commonly refers to clinical signs resulting from low cardiac output and inadequate tissue perfusion, including weakness, lethargy, and prerenal azotemia. Insufficient BP or renal perfusion also triggers renal sodium retention. Backward failure refers to the failure of the heart to empty blood from the veins, leading to elevated venous and capillary pressures. The consequences of venous congestion include pulmonary edema, ascites, and pleural effusion, creating the well-recognized syndromes of left-sided, right-sided, or biventricular CHF. Cardiogenic shock is diagnosed when patients have severe signs of both forward and backward HF accompanied by systemic hypotension.

The anatomic location of the disease provides a useful framework for classification when considering the morphologic cardiac diagnosis. Heart diseases are commonly delimited as diseases of the pericardium, myocardium, endocardium and valves, impulse forming and conduction system, or vascular system. In dogs the most important diseases leading to HF are chronic degenerative valvular heart disease (DVD or valvular endocardiosis) causing mitral and tricuspid regurgitation, idiopathic or genetic dilated cardiomyopathy (DCM), pericardial effusion often caused by neoplasia, and pulmonary hypertension from heartworm disease. Taken as a group, congenital heart defects that include patent ductus arteriosus, subaortic stenosis,

and various valve malformations can be considered important causes of HF in dogs. Cardiac rhythm disturbances often complicate structural heart disease, with atrial fibrillation (AF) and ventricular tachycardia representing the best examples. The diagnosis and management of these disorders are discussed in some detail in chapters throughout this section.

ESTABLISHING THE CARDIAC DIAGNOSIS IN HEART FAILURE

When a clinician suspects HF based on clinical signs, the first step in treatment is *establishing the underlying heart disease* responsible and determining the severity of the condition. This information allows the clinician to provide the most specific and appropriate therapy and a more accurate prognosis.

The reason for HF generally can be determined by appreciating the epidemiologic risk for heart disease (breed and age); the physical examination findings, emphasizing arterial and venous pulses, cardiac and thoracic auscultation, and abdominal palpation; the radiographic findings that support a diagnosis of HF and rule out bronchopulmonary or thoracic disease; and the results of 2D echocardiographic imaging for assessment of heart size, function, and overt lesions. Doppler echocardiographic studies are often important adjuncts to 2D and M-mode echocardiography in the assessment of some patients. Routine electrocardiography has a low specificity for heart disease in dogs but is pivotal when cardiac rhythm disturbances are suspected. Since BP may be elevated as a comorbid disease or low related to forward failure, noninvasive BP should be determined. Routine laboratory tests (complete blood count and serum chemistry) should also be obtained from suspected HF patients. In some patients a circulating biomarker such as N-terminal, pro-brain natriuretic peptide (N-pBNP) may assist in the differential diagnosis, assuming the laboratory has well-established cutoffs for HF (as opposed to simple heart disease).

In the vast majority of canine patients the underlying reason for HF is chronic atrioventricular valvular disease (see Chapter 172) or DCM (see Chapters 174 to 176). Pericardial disease (see Chapter 181) is an underrecognized cause of CHF and should be in the differential diagnosis of any dog with right-sided CHF or pleural effusion. In heartworm-endemic regions pulmonary hypertension caused by dirofilariasis should be a consideration for right-sided CHF. If the underlying reason for HF is not obvious from the workup described previously, the patient should be stabilized (e.g., diuresed) and referred to a cardiologist for a second opinion. If referral is not feasible, at a minimum thoracic radiographs taken before and after any therapy should be reviewed within the context of the history by a radiologist or cardiologist.

FUNCTIONAL CLASSIFICATION OF HEART DISEASE AND FAILURE

Because the clinical signs of HF are similar regardless of the underlying disease that causes the heart to fail, classification systems that grade the severity of HF or stage patients with HF have developed independently of anatomic or

etiologic diagnoses. These *functional classifications of HF* include the four-stage New York Heart Association (NYHA) and the three-stage International Small Animal Cardiac Health Council (ISACHC) classifications along with some newer proposals described later in the chapter. Functional classification systems are designed to provide a framework for discussing and comparing the clinical signs of patients in HF and to some extent estimating the need for various therapies. These classification schemes vary in their details but serve to describe a semiquantitative method for judging the severity of a patient's clinical signs that can be generalized as follows:

- *Class I:* Heart disease is present, but no clinical signs are evident even with exercise.
- *Class II:* Heart disease is causing clinical signs only with strenuous exercise.
- *Class III:* Heart disease is causing clinical signs with routine daily activities or with mild exercise.
- *Class IV:* Heart disease is causing severe clinical signs even at rest.

Class I dogs are commonly identified in practice as the older but healthy dog with chronic mitral regurgitation (MR). Class II dogs are certainly underrecognized. Although exercise limitations are probably the most sensitive finding for a failing heart, most dogs do not engage in maximal exercise, and clients often disregard reduced exercise capacity as “just slowing down with age.” Class III dogs have consistent clinical signs attributed to heart disease (classes II and III are combined in the ISACHC scheme). Dogs with class III left-sided HF pose a diagnostic dilemma in terms of distinguishing cough caused by primary tracheobronchial disease from that caused by left main-stem bronchial compression or pulmonary edema. Class IV dogs (class III in ISACHC scheme) are in obvious CHF and present more of a therapeutic than a diagnostic challenge.

Although some dogs with heart disease follow an orderly progression through a functional classification, these schemes allow the patient to move freely in both directions. For example, movement from class IV to class III or II might follow diuretic therapy. Progression from class I to class III or IV could occur following a large dietary salt load, the sudden structural deterioration of a mitral valve, or the onset of a hemodynamically significant arrhythmia such as AF.

The American College of Cardiology (ACC) and the American Heart Association (AHA) have developed a new approach to staging HF that emphasizes the progressive nature of most of the diseases that cause HF. This scheme (modified from *J Am Coll Cardiol* 38:2101, 2001) can be adapted for veterinary use as follows:

- *Stage A:* Patients are at high risk for the development of HF but without apparent structural abnormality at the present time. Examples would include cavalier King Charles spaniels; boxers; Doberman pinschers; and other dogs belonging to breeds, families, or demographic groups predisposed to heart disease.
- *Stage B:* Patients have a structural abnormality but have never had symptoms of HF. Examples include the asymptomatic miniature poodle with a murmur

of MR, an asymptomatic Doberman pinscher with systolic myocardial dysfunction and left ventricular dilatation, and an asymptomatic boxer with significant right ventricular ectopy on a Holter electrocardiogram (ECG).

- *Stage C:* Patients have a structural abnormality and current or previous clinical signs of HF. This stage includes all patients that have had an episode of clinical HF. They stay in this stage despite improvement of their clinical signs with standard medical therapy.
- *Stage D:* Patients have clinical signs of CHF that are refractory to standard treatment (defined in humans as standard doses of diuretics, angiotensin-converting enzyme [ACE] inhibitors, β -blockers, and digoxin).

The ACC/AHA staging system modified for dogs (and adopted by the European Society of Veterinary Cardiology and the American College of Veterinary Internal Medicine Study Groups) emphasizes that progressive structural abnormalities underlie the pathogenesis of HF. This system is meant to encourage a program of HF management and education that supports early detection and screening for heart disease and provides a loosely defined “stepped” plan of treatment intensification that may be applied appropriately as heart disease progresses. This program defines current *standard treatment* in humans as combination therapy of furosemide, an ACE inhibitor, digoxin (if no known contraindications exist), and a β -adrenergic blocking agent. What constitutes standard therapy for canine HF is still debated, but the principles of the classification still hold. This staging system departs from older functional classifications because a patient can still progress suddenly from stage B to stage C or even D, but that path cannot be traveled in reverse.

The modified ACC/AHA staging system provides a useful framework for thinking about heart disease and HF that is more analogous to the standard clinical approach to cancer. The parallels are obvious: screening and identification of patients that are known to be at risk for cancer (stage A); the identification and treatment of patients with in-situ disease (stage B); and the identification and treatment of patients with established (stage C) or widespread (stage D) disease.

FRAMEWORK FOR MANAGING HEART FAILURE IN DOGS

Considering what we know regarding the origin, pathogenesis, progression, and response to therapy of the common acquired heart diseases of dogs (valvular heart disease and DCM), a therapeutic framework for managing heart disease and HF in dogs should include specific diagnostic, treatment, and educational plans for each stage of heart disease. Management plans should consider the natural history of the disease and carefully weigh what is known regarding the potential benefits and risks of medications and their combinations when used in a specific clinical setting. This general scheme can be used to establish management plans for any type of heart disease. A brief example of a management strategy using these principles is described in the following paragraphs for DVD, with some additional comments inserted concerning the dog with DCM.

Stage A: Screening for Dogs At Risk But Without Clinical Signs

Cavalier King Charles spaniels, dachshunds, and other small breeds at increased risk for the development of chronic valvular heart disease should be screened by thorough cardiac auscultation. In otherwise healthy animals, the absence of a typical holosystolic murmur of mitral valve insufficiency over the left cardiac apex adequately rules out *significant* disease. This screening is repeated annually. If a screening examination is positive, the patient proceeds to stage B.

It should be emphasized that this stand-alone auscultation approach is inappropriate as the screening test for breeds at risk for cardiomyopathy. These disorders require echocardiography and possibly an ambulatory (Holter) ECG to obtain a reasonable sensitivity for diagnosis.

Stage B: Heart Disease Is Evident From Screening Examination

Now that heart disease (in this case a murmur of MR stemming from probable DVD) has been identified, the cardiac diagnosis is further refined by additional evaluations. The potential for early therapy is also considered.

Staging the severity of DVD includes imaging of the heart. In general one can recommend acquisition of high-quality thoracic radiographs exposed with a standard technique (e.g., right lateral and dorsoventral projections) if for no other reason than to have a comparison should the dog eventually develop respiratory signs. This approach improves differentiation of cardiac from primary respiratory causes of cough or dyspnea.

Depending on the circumstances, a two-dimensional echocardiogram might also be obtained to confirm the presence of anatomic valve lesions and provide additional quantitation of heart size and function. A Doppler echocardiographic study can confirm the auscultatory diagnosis and offers semiquantitative measures of severity. An echocardiogram is certainly indicated when the diagnosis is uncertain (e.g., is the MR murmur caused by endocardiosis or DCM in a cocker spaniel?). Furthermore, an echocardiogram is probably indicated in any dog younger than 6 years of age with a murmur to rule out the possibility of congenital heart disease. As with any system, common sense must also apply; and this last guideline would probably be inappropriate for a cavalier King Charles spaniel of 4 to 6 years of age, in which valvular endocardiosis may become evident in young adult dogs.

If thoracic radiographs are normal in the dog with a typical MR murmur of DVD, no further workup is indicated (although some clinicians measure arterial BP to screen for hypertension). Repeated imaging would be suggested in 1 year. However, if imaging demonstrates significant cardiomegaly or echocardiography shows hemodynamically important mitral valve regurgitation with left atrial enlargement, it would be prudent to consider the current evidence and treatment recommendations before the onset of clinical signs. Concurrently the client should be educated regarding the presence of significant heart disease; treatment options; and their potential impact of therapy on prognosis, cost, and quality of life.

Considering the current framework and example, how might one manage the dog with DVD and associated cardiomegaly? A number of therapeutic possibilities can be considered. Our personal recommendations and specific treatment guidelines are summarized later in this chapter.

Angiotensin-Converting Enzyme Inhibitors (Enalapril, Benazepril, Ramipril, Quinapril, and Lisinopril)

Early use of ACE inhibitors is still controversial. Evidence based on randomized, prospective, blinded clinical trials in dogs with chronic valve disease is mixed. One study (SVEP, Kvart et al., 2002) showed no benefit in delaying onset of CHF, whereas results from another trial (VETPROOF, Atkins et al., 2007) show a possible mild benefit. This was equivalent to approximately a 3-month extension of time before the onset of HF over a 3-year period. It should be emphasized that these points are pertinent only to the small-breed dog with DVD. Dogs with idiopathic DCM or large-breed dogs with significant MR might benefit from ACE inhibition based on some clinical reports. In an abstract from Guelph reporting results of an open-label trial, enalapril delayed onset of CHF for Doberman pinschers.

β -Blockers (Atenolol, Metoprolol, Carvedilol)

Therapy with β -blockers in stage B disease (or any other stage) is still debated because there are no data from sufficiently powered, controlled clinical trials in client-owned animals with DVD and only small studies in dogs with spontaneous DCM. Experimental evidence from relatively acute studies of induced mitral valve disease in larger dogs and from models of experimental canine myocardial disease, as well as extrapolation from human clinical trials, suggests a potential benefit of β -blockade. Overall these are relatively low grades of evidence on which to recommend a therapy. Proof of efficacy in asymptomatic DVD is difficult to obtain because the time course of chronic MR often exceeds 4 to 5 years before onset of CHF. In this ambiguous situation some cardiologists initiate a β -blocker therapy in asymptomatic dogs with moderate-to-advanced DVD; based on a recent survey of North American veterinary cardiologists, most do not. Again, dogs with DCM or large-breed dogs with advanced MR represent different patient groups, and it is more common for cardiologists to prescribe β -blockade in these groups aiming for myocardial protection. However, it is emphasized that no definitive studies have been published to support treatment with β -blockers in dogs with HF.

Digoxin

Cardiac glycosides are not recommended since there are no clinical trials and little experimental evidence supporting use of digoxin at this stage of disease in DVD (or in canine DCM).

Pimobendan (Vetmedin)

This inodilator is not recommended by most cardiologists at this stage of disease. Currently two clinical trials are investigating the efficacy and effects of pimobendan in asymptomatic dogs with DVD and with preclinical DCM.

Spironolactone

This aldosterone antagonist generally is not recommended based on absence of any convincing clinical evidence of efficacy at this stage of disease. Spironolactone demonstrates no significant diuretic effects in dogs with normal aldosterone levels (i.e., dogs not in CHF).

Neutraceuticals (Taurine, Carnitine, Coenzyme Q₁₀, ω -3 Fatty Acids, or Fish Oils)

These drugs generally are not recommended in dogs with DVD based on absence of any convincing clinical evidence at this stage of disease. Conversely, in particular canine breeds with primary myocardial diseases, there may be some indication for supplementation (see Chapter 159 for details).

Sodium (Salt)-Restricted Diet

Dietary modifications during stage B are controversial. Modest salt restriction, preferably without protein restriction (e.g., a "senior diet") may be of potential benefit in advanced DVD since experimental studies show abnormal sodium handling before the onset of HF. However, considering the long time course of chronic MR, this overall benefit is likely to be very small.

Stage C: Hemodynamically Significant Heart Disease With Signs of Heart Failure

Many dogs with DVD (and most with DCM) are first diagnosed and treated at this stage of disease. These patients usually are presented to the veterinarian because the owner has identified apparent dyspnea, often associated with orthopnea or a history of not wanting to lie down. Coughing is often present in the history along with days or weeks of exercise intolerance, lethargy, reduced appetite, and weight loss. The heart rate is often elevated for a resting dog (>140 beats/min), as is the respiratory rate (>40/min). Examination likely indicates cardiac abnormalities, including murmur(s) in dogs with DVD and possibly arrhythmias and gallop sounds. Lungs may crackle from pulmonary edema, but this is not always evident. In right-sided CHF jugular distention, hepatomegaly and possibly ascites may be evident.

If the animal is not too anxious or dyspneic, confirmation of the diagnosis with thoracic radiographs is always indicated as are other diagnostics as previously discussed. When life-threatening CHF is evident, aggressive management may be required as described for stage D and later in the treatment plans. For dogs that have been followed chronically through the various stages of heart disease, the likelihood of identifying early signs of HF is relatively high, and many of these dogs can be given a single dose of furosemide and sent home receiving oral medications for HF.

Unquestionably there are dogs with DVD in which the precise cause of coughing is not obvious. In these patients a more "restrained" HF treatment plan is indicated initially. This consists of a low daily dosage of furosemide plus an ACE inhibitor. This therapy generally improves signs when the problem is HF and thereby provides insight into the basis for coughing. Some dogs without overt CHF but affected by left main-stem bronchial compression also improve with this therapy and can be managed for some time with these two

drugs and occasional use of cough suppressants. However, in many canine patients there is no doubt about the diagnosis of CHF, and treatments that have been shown to reduce clinical signs and/or prolong life are recommended.

Most dogs with stage C failure are started on standard canine HF therapy. Based on the evidence and a recent survey of cardiologists, this includes preload reduction (furosemide), an ACE inhibitor, and pimobendan. There are clinical trials that show efficacy of these treatments in dogs with both advanced DVD and DCM. Some still prefer to prescribe an ACE inhibitor versus pimobendan, but a cogent argument can be made for starting both drugs simultaneously along with furosemide since these agents work differently. Spironolactone is often prescribed by cardiologists for advanced CHF, and this drug has recently been approved for treatment of CHF in dogs in Europe (although the specific trials are unpublished at this time). Digoxin has largely been supplanted by pimobendan, but cardiac glycosides may be useful in the setting of atrial arrhythmias or for potential benefits in sensitizing baroreceptors. As previously mentioned, the risk-benefits of a β -blocker in stable stage C (or D) failure is unresolved. If used, β -blockade should be delayed until the patient is free of any congestion and obviously is stable on a recheck examination. Drugs such as carvedilol should be started at low doses and gradually up-titrated.

Even with successful resolution of clinical signs, these patients remain on chronic drug therapy and never fall below a stage C classification. The diuretic dosage may be adjusted down to the lowest level needed. Chronic HF therapy is aimed at achieving two principal goals: (1) solidifying and maintaining hemodynamic improvements with a return to routine activities without clinical signs of HF; and (2) prolonging life by reducing the ongoing damage to the heart muscle inflicted by neurohormonal activation, as long as the therapy does not impair quality of life.

Stage D: Refractory Heart Failure

In the acute setting with previously untreated patients, it is impossible to tell which dogs will be refractory to treatment. For this reason stages C and D are considered together with respect to in-hospital management of HF. Chronic progression of stage C to stage D produces patients that are refractory to standard therapy with furosemide, spironolactone, ACE inhibition, pimobendan, and possibly β -blockers. Treatment of refractory HF from any cause is a challenging and potentially frustrating endeavor for both veterinarians and clients. A thorough search for factors commonly involved in the progression of HF is indicated, including anemia, hypertension, infection, and iatrogenic thyrotoxicosis.

Therapeutic principles for stage D failure include maintenance of whatever hemodynamic and cardioprotective regimens were well tolerated during stage C. It becomes important to evaluate critically client compliance, the current drug regimen, and the dosages. For example, it may be possible to "optimize" the dosages of the ACE inhibitor (to 0.5 mg/kg orally [PO] q12h for enalapril or benazepril), pimobendan (to 0.3 mg/kg PO q12h or 0.6 mg/kg daily divided TID), or spironolactone (2 mg/kg daily). If renal function is still normal,

furosemide dosages can be increased, and digoxin can be added for its inotropic and baroreceptor activities. Regular subcutaneous dosing of furosemide may provide some additional benefit as described in the treatment plans. Others prefer to cautiously add hydrochlorothiazide (1 to 2 mg/kg QOD initially), although sequential nephron blockade of sodium resorption with three diuretics often predisposes to acute renal failure and marked electrolyte depletion. If a β -blocker is part of the regimen, the potential that the dose is too high should be considered. If a new arrhythmia has developed, especially AF, the addition of diltiazem to control ventricular rate may be pivotal (see Chapter 161 and following paragraphs). Some centers attempt direct current cardioversion to improve hemodynamics in dogs with CHF and AF. Although very effective in dogs with AF alone (see Chapter 164), in our experience some dogs with advanced heart disease do not cardiovert, and the majority revert. For dogs with documented severe pulmonary hypertension and exertional collapse, syncope, or advancing ascites or pleural effusion, a drug such as sildenafil (1 to 3 mg/kg PO q8–12h) or another phosphodiesterase V inhibitor may be useful for a trial course of therapy. When borderline or overt systemic hypertension complicates CHF, vigorous BP reduction should be undertaken (see Chapter 159). This generally involves a full dose of an ACE inhibitor and up-titrated doses of amlodipine (starting at 0.05 to 0.1 mg/kg PO q12h) to reduce systolic BP to the 90- to 120-mm Hg range.

The use of additional arterial or venous dilators, positive inotropes, or sophisticated electrical or mechanical circulatory aids may be of potential benefit for some clients and patients. Cardiologists may be helpful in discussing extralabel therapies or new drugs that may provide benefit. Cardiac pacemaker resynchronization therapy, valve repair, and other novel strategies may gain some foothold in advanced veterinary care. Consultation with or referral to an HF center or veterinary cardiologist is suggested if these resources are available.

For dogs with life-threatening pulmonary edema or cardiogenic shock, hemodynamic optimization and maintenance of BP and tissue oxygenation are the initial hospital treatment goals. Oxygen is administered. Thoracocentesis or abdominocentesis is indicated for large pleural effusions or tense ascites. Medical treatments may include intravenous boluses of furosemide supplemented by constant-rate infusions (CRIs); addition of nitroglycerin or sodium nitroprusside for acute load reduction; or infusion of dobutamine to manage cardiogenic shock. Details of these treatments follow.

DRUGS USED IN THE THERAPY OF CANINE HEART FAILURE

Cardiovascular therapy involves the use of a relatively large number of drugs. Some treatments for CHF elicit rapid hemodynamic effects (furosemide, dobutamine, sodium nitroprusside, and pimobendan). Others modulate neurohormonal or inflammatory mediators of CHF (ACE inhibitors, spironolactone, β -blockers, and fatty acids). Still others may be used for pure symptom relief (airway medications, sedatives, and oxygen). Understanding the

clinical use of these drugs singly and in combination with others is critical.

Diuretics

Diuretics and dietary sodium restriction are critical for management of CHF. Furosemide (2 to 6 mg/kg intravenously [IV], intramuscularly [IM], subcutaneously [SQ], PO) is a potent loop diuretic used first for mobilization of edema and chronically to prevent fluid retention (on a BID-TID basis). Given initially by the intravenous or intramuscular route every 2 to 6 hours, furosemide also can be infused (after the initial bolus) for life-threatening pulmonary edema (6 to 8 mg/kg CRI over 24 hours). This approach appears to increase urine volume with less electrolyte disturbance. Spironolactone (2 mg/kg PO in one daily or two divided doses) is a very weak diuretic used mainly for cardioprotective and potassium-sparing actions and is given as cotherapy with furosemide in chronic management of CHF. Some clinicians use hydrochlorothiazide (starting at 1 to 2 mg/kg once daily or QOD) for refractory edema or ascites. Adverse effects of diuretics include polydipsia, polyuria, reduction in BP, azotemia, electrolyte depletion, and elevated blood potassium (with spironolactone). A thiazide can be dangerous when added to furosemide and spironolactone, and serum chemistries should be monitored carefully when three diuretics are prescribed. In the future nesiritide (genetically engineered, human-BNP) may be used as an adjunct to diuretic therapy of severe CHF.

Vasodilators and Angiotensin-Converting Enzyme Inhibitors

The ACE inhibitors and vasodilators are mainstays of CHF therapy. Venodilation pools blood in systemic veins and reduces venous pressure, whereas arterial dilation reduces BP and left ventricular afterload. MR is usually reduced considerably by arterial vasodilation and lowering of diastolic BP.

ACE inhibitors, including benazepril, enalapril, and ramipril, are typically dosed at 0.5 mg/kg PO once or twice daily). These drugs have modest vasodilator effects but importantly reduce angiotensin II and aldosterone levels and protect the cardiac muscle. The ACE inhibitors are the vasodilator drugs of choice for chronic CHF. In our practice we typically start at 0.25 mg/kg orally every 12 hours (or 0.5 mg/kg once daily) and increase the dosage to 0.5 mg/kg orally every 12 hours at the time of first follow-up if the drug is well tolerated. Major adverse effects include reduced BP, elevated blood urea nitrogen, and elevated serum potassium.

Direct vasodilator drugs (with usual dosages) include 2% nitroglycerin ointment ($\frac{1}{4}$ to 1 inch topically q12h), sodium nitroprusside (0.5 to 5 mcg/kg/minute), and sildenafil (1.0 to 3 mg/kg PO q8–12h). Nitrates increase nitric oxide, and the phosphodiesterase V inhibitor sildenafil prevents degradation of the second messenger of this system (cyclic guanosine 5'-monophosphate). Nitrates are used for hospital therapy of CHF; sildenafil and related drugs are used for treatment of severe pulmonary hypertension (peak pressure >80 mm Hg).

L-arginine, the precursor of nitric oxide, is supplemented (empiric canine dose: 250 to 500 mg PO TID) when severe pulmonary hypertension is documented.

Amlodipine (0.05 to 0.1 mg/kg PO q12h in dogs with CHF; higher dosages for systemic hypertension) is a calcium channel blocker with vascular selectivity. It is used mainly in dogs with intercurrent systemic hypertension that do not respond sufficiently to an ACE inhibitor and diuretic therapy. Amlodipine can also provide additional vasodilation to unload the left ventricle in end-stage MR. The main adverse effect of all arterial vasodilator drugs is systemic hypotension. Some drugs, including amlodipine and hydralazine (1 to 3 mg/kg PO q12h), also may cause reflex neurohormonal activation.

Positive Inotropic Drugs

The positive inotropic drugs include catecholamines (dobutamine, dopamine), digoxin, and pimobendan. Dobutamine (2.5 to 10 mcg/kg/minute) is reserved for dogs with cardiogenic shock (BP <80 to 85 mm Hg; hypothermia; CHF) and is infused in 5% dextrose solution for 24 to 48 hours. Specifics on using dobutamine are outlined in Cardiogenic Shock later in the chapter.

Digoxin (0.005 to 0.0075 mg/kg PO q12h in dogs with normal renal function) is a modest positive inotropic drug that also slows heart rate. The main indication for digoxin is advanced CHF or CHF with AF, in which its vagal enhancement helps to slow atrioventricular nodal conduction and heart rate by improving baroreceptor sensitivity. Adverse effects of digoxin (i.e., anorexia, vomiting, diarrhea, depression, and cardiac arrhythmias) are best avoided by monitoring therapy with a serum digoxin level. A trough level of 0.8 to 1.2 ng/ml is the recommended target. Relative contraindications to digoxin use are complex ventricular ectopia, azotemia, sinus node dysfunction, and preexistent atrioventricular block.

Pimobendan (Vetmedin 0.2 to 0.3 mg/kg PO q12h; in end-stage CHF may administer off label) is a potent, orally administered inotropic drug with vasodilator properties. It is classified as a calcium sensitizer with phosphodiesterase III inhibition. Now widely available, pimobendan has largely replaced digoxin for management of moderate-to-severe CHF in dogs. No consistent adverse effects of pimobendan have been reported; however, clients may notice the heart "pounding" at higher dosages. Furthermore, it is likely that some dogs will experience an increase in ventricular ectopy following therapy with pimobendan (or any positive inotropic drug). The importance of any proarrhythmic effect awaits further study.

β -Adrenergic Blockers

β -Blockers, particularly carvedilol and metoprolol (long-acting) are used increasingly in HF to protect the heart muscle and with chronic use may improve left ventricular ejection fraction in cardiomyopathy. In model studies β -blockers are cardioprotective, but this was not evident in a preliminary clinical study in dogs with DCM. Carvedilol is now available in a very affordable generic form in some countries. It is a nonspecific β -blocker

with weaker α -adrenergic blocking effects. Also a potent antioxidant drug, carvedilol may protect myocardium from cytokine injury. Although β -blockers should never be used in uncontrolled CHF, gradual dose up-titration is possible in many dogs. For example, after an initial 2- to 4-week treatment to stabilize CHF, a starting dose of carvedilol (0.05 to 0.1 mg/kg PO once or twice daily) is usually well tolerated. The dosage may be increased slowly in DCM every 2 to 4 weeks, aiming for a target dosage of about 0.5 to 0.6 mg/kg orally every 12 hours. Higher doses are tolerated in asymptomatic dogs and in dogs with DVD in which myocardial dysfunction is usually less severe. Only very low doses tend to be tolerated in many dogs with severe DCM. Concurrent use of pimobendan seems to offset the negative inotropic effects of β -blockers. Major adverse effects are weakness, hypotension, bradycardia, and worsening of edema or effusions. Better known drugs such as atenolol are potentially beneficial in models of canine left ventricular dysfunction, but little is known clinically about their use for this purpose in canine HF.

Antiarrhythmic Drugs

Antiarrhythmic drugs are not used specifically for treatment of CHF. However, in AF heart rate control is usually gained by combination of digoxin plus diltiazem (starting dosage of diltiazem is 0.5 mg/kg PO q8h up-titrated to as high as 2 mg/kg PO q8h or 6 mg/kg daily of a long-acting preparation divided BID). Often the addition of carvedilol further slows the ventricular rate response to AF, allowing for a dosage reduction of diltiazem. Both drugs are negative inotropes and must be used carefully. Some clinicians prefer other β -blockers for control of heart rate in AF such as atenolol (starting dose of 0.1 mg/kg PO q12h in CHF with dosage up-titration to 0.25 to 0.5 mg/kg PO q12h).

Management of ventricular arrhythmias in the setting of CHF is difficult. Sotalol and many other antiarrhythmic drugs are negative inotropes and are best avoided if possible. Intravenous lidocaine (2 to 4 mg/kg intravenous boluses to 8 mg/kg; 50 mcg/kg/minute CRI) can be used in the hospital, and mexiletine (5 to 8 mg/kg PO q8h) may be effective if adverse effects (anorexia, vomiting, and tremors) are not severe. Reduced hepatic blood flow may lead to toxicity. Mexiletine and long-acting formulations of procainamide (12 to 20 mg/kg PO q8h) are ventricular antiarrhythmic drugs with minimal myocardial depression; however, other adverse effects, including anorexia and gastrointestinal signs, can be observed. Mexiletine can elevate liver enzymes in some dogs. Amiodarone is used increasingly for life-threatening arrhythmias at about 10 mg/kg orally once daily for 2 weeks and 4 to 6 mg/kg orally once daily thereafter. Liver enzymes/function tests and a complete blood count should be followed quarterly in dogs receiving amiodarone. Severe liver toxicity has been observed. The drug has a very long elimination half-life; therefore adverse effects may be persistent. Management of rhythm disturbances are discussed in more detail in Arrhythmias in CHF later in the chapter and in Chapters 161, 162, and 164).

SPECIFIC TREATMENT PLANS FOR CANINE HEART FAILURE

The management of HF in dogs involves consideration of the underlying cardiac diagnosis, the stage of heart disease, and the current clinical findings. Some dogs with stages C or D (or NYHA modified class IV) HF will likely succumb from tissue hypoxia, hypotension, or arrhythmia if not promptly treated in the hospital setting. Other patients with less severe signs are simpler to manage and often can be treated on an outpatient basis. There are few studies objectively assessing HF therapy in dogs; nevertheless, clinicians need to make decisions about patient management that are decisive and specific. In that vein the following are personal guidelines for hospital and home management of the dog with HF.

Asymptomatic Heart Disease

As noted previously, early introduction of cardiovascular drug therapy in preclinical or asymptomatic dogs with stage B heart disease is controversial. For dogs with DCM that is well-defined by echocardiography, we prescribe cardioprotective drugs in an attempt to delay onset of overt HF. We prescribe both an ACE inhibitor (enalapril 0.5 mg/kg PO q12h) and a β -blocker (usually carvedilol up-titrated every 2 weeks as described previously) to dogs with proven ventricular dysfunction caused by DCM. Large-breed dogs with chronic MR and demonstrable cardiomegaly or left ventricular dysfunction are treated as if they have occult DCM.

The SVEP and VETPROOF trials (Kvart et al., 2002; Atkins et al., 2007), together suggest a small benefit at best for small-breed dogs with preclinical DVD. We believe that, if an ACE inhibitor is started, it should be in a dog with well-advanced MR from DVD. We recommend regular chest radiographs or quantitative 2D echocardiograms to identify moderate-to-severe MR or a marked interval change in heart size compared to prior evaluations. In advanced or progressive cases we begin an ACE inhibitor empirically. We recommend a full dose of 0.5 mg/kg of enalapril/benazepril every 12 hours, considering that some dogs in these published trials were treated with relatively low doses. We also screen older dogs for hypertension, initiate ACE inhibitor therapy, and evaluate kidney and adrenal functions in dogs with hypertension and advanced MR.

We do not advocate the use of inotropic drugs such as digoxin or pimobendan in preclinical stage B unless radiographs indicate that pulmonary edema is imminent or left ventricular systolic dysfunction is markedly reduced and there is associated exercise intolerance. Breeds at risk for fulminant CHF such as the Doberman pinscher would be likely candidates for pimobendan in these situations. As stated earlier, clinical trials are under way to address the issue of early intervention with pimobendan in dogs with DCM and DVD.

Acute Pulmonary Edema

When CHF leads to life-threatening pulmonary dysfunction, the combination of parenteral furosemide, oxygen,

topical nitroglycerin (or sodium nitroprusside), and sedation with butorphanol represents the initial treatment plan applicable to most dogs with CHF regardless of cause. In our experience butorphanol (0.25 mg/kg IM, repeated in 30 to 60 minutes if needed) is the safest sedative to use in this setting. With this protocol diuresis is initiated; hemoglobin oxygen saturation is increased, ventricular preload is reduced, the tendency toward pulmonary edema is decreased, and anxiety is relieved. If patients are heavily sedated, the torso is positioned in sternal recumbency, the chin supported with a towel or soft pad, the neck gently extended, and nasal oxygen inserted for better oxygenation.

A relatively high initial furosemide dose (4 to 5 mg/kg IV) is administered in cases of severe CHF because renal blood flow may be reduced. The dog should be checked every 30 minutes for evidence of diuretic effect (by observation for urination and palpation of the urinary bladder). Once diuresis ensues, the dose is reduced to 2 mg/kg every 8 to 12 hours intravenously or intramuscularly. In life-threatening pulmonary edema (i.e., severe dyspnea with poor response to initial therapy, expectoration of fluid, or "white-out" lung on chest radiograph), a CRI of furosemide and afterload reduction with nitroprusside (or oral hydralazine) should be considered.

Although topical nitroglycerin may function as a venodilator, reduction of systemic BP is one of the most effective methods for reducing the severity of MR. The addition of nitroprusside is indicated in cases of pulmonary edema characterized by severe dyspnea, hemoptysis, or expectoration of pink froth with marked alveolar infiltrates on the chest radiographs, especially those that don't improve clinically over the first 30 to 60 minutes of hospitalization (Fig. 171-1). The main contraindication to potent afterload reducers such as nitroprusside is preexistent hypotension (<90 mm Hg systolic BP). Frequent BP monitoring should be scheduled when administering nitroprusside, and the clinician should titrate the infusion dose to a systolic pressure of 85 to 100 mm Hg (as well as to clinical signs). Treatment duration is 24 hours (or less) in most cases. Less potent and less controllable alternatives to nitroprusside include an ACE inhibitor and oral hydralazine (0.5 to 2 mg/kg q8-12h). Initiation of pimobendan in the setting of acute pulmonary edema also can be considered since this drug reduces both afterload and preload.

Cardiogenic Shock

The finding of cardiogenic pulmonary edema or pleural effusion with severe hypotension (BP <80 mm Hg) and other indicators of low cardiac output (pallor, hypothermia, depression, and elevated blood lactate) is highly suggestive of cardiogenic shock. Dogs with DCM are most likely to be presented this way. Other potential causes include myocardial infarction, overdose of a β -blocker, and massive pulmonary embolus as might occur following treatment for adult heartworms or after a spontaneous pulmonary thromboembolism.

Initial treatment is the same as discussed previously, starting with furosemide-oxygen-nitroglycerin therapy. Since these patients are hypotensive and often very depressed, sedation is rarely needed. The need for

Fig. 171-1 **A**, Thoracic radiograph from a dog with severe pulmonary edema associated with DVD and ruptured chorda tendinea. **B**, Thoracic radiograph from the same dog 20 hours after aggressive diuresis and load-reducing therapy with sodium nitroprusside. The dog was released from the hospital.

thoracocentesis should be determined since dogs with cardiogenic shock may have both pulmonary edema and pleural effusion. Volume infusion is inappropriate to raise BP in this setting because it only worsens edema. In most cases the main goal is stimulation of myocardial contractility to improve pump function and facilitate diuresis.

In this situation the most important therapy to administer (along with diuretics) is a potent positive inotropic drug with a goal of increasing BP by augmenting cardiac output. No other drug seems as effective as dobutamine in this setting of cardiogenic shock. However, cotherapy with pimobendan may be very beneficial and can help dobutamine create a “bridge” to allow for long-term therapy with pimobendan, an ACE inhibitor, and diuretics. Digoxin is too weak to have much effect in cardiogenic shock and is only initiated in the setting of AF (for heart rate control).

Dobutamine (or dopamine if preferred) is administered as an intravenous CRI, starting at 2.5 mcg/kg/minute and increasing the infusion every 30 minutes until systolic BP is 90 mm Hg. The typical end point is 5 to 10 mcg/kg/minute. At higher infusion rates vasoconstriction and increased heart rate become increasingly important as factors that increase BP. However, neither vasoconstriction (which creates an afterload mismatch) nor sinus tachycardia (which increases oxygen demand) represents an advantage to a failing left ventricle. Therapeutic effects of dobutamine include increased cardiac output, elevated BP, increased tissue perfusion (better color and shorter refill time, stronger pulse), increasing body temperature, and improvement in attitude and strength. Adverse effects necessitating dose reduction include increasing heart rate, excessive vasoconstriction, and induction of extrasystoles. Seizure activity and vomiting are observed infrequently in dogs.

Once the BP is stable (systolic pressure in the 90– to 100–mm Hg range), other vasoactive drugs, either nitroprusside or an ACE inhibitor, can be initiated, and pimobendan started. After 24 to 48 hours of dobutamine therapy, the dobutamine rate is reduced by 50% every

2 to 4 hours, and after reaching 1 to 2 mcg/kg for 2 to 4 hours the infusion is discontinued.

Arrhythmias in Congestive Heart Failure

The most common rhythm considerations are atrial premature complexes, AF, ventricular ectopy (premature ventricular complexes and ventricular tachycardia), and sinus node disease in breeds at risk (e.g., miniature schnauzers, cocker spaniels, and West Highland white terriers), wherein digoxin and β -blockers should be avoided. Isolated atrial and ventricular premature complexes may respond to treatment of CHF and are not aggressively suppressed with drugs.

Digoxin is the initial drug chosen to control heart rate in dogs with AF and CHF; however, additional therapy is usually needed to prevent deleterious effects of persistent tachycardia. After confirming the rhythm diagnosis of AF with an ECG, digoxin can be started using a maintenance dosage (0.005 to 0.0075 mg/kg PO q12h) or a modified loading dose (0.01 mg/kg PO BID for two doses). To slow the heart rate further, after 24 to 48 hours of HF stabilization the calcium channel antagonist, diltiazem, is added to block the atrioventricular node (starting at 0.5 mg/kg PO q8h). Diltiazem added to digoxin better controls ventricular rate response. Provided systolic BP is higher than 90 mm Hg, one can rapidly up-titrate the dose of diltiazem at each subsequent dosing interval (i.e., increase the dose every 8 hours). Usual target doses of diltiazem are 1 to 2 mg/kg PO q8h (or an equivalent dose of long-acting diltiazem divided BID) to obtain a “resting” hospital heart rate of 120 to 160 beats/min. Some dogs require dosages as high as 6 mg/kg daily in divided doses. If follow-up examinations indicate stable CHF, a β -blocker also may be used to slow heart rate in AF. The clinician must beware of the negative inotropic effects of diltiazem and β -blockers.

Another option for treatment of AF is direct current cardioversion. Pros and cons of such therapy should be

discussed with a cardiologist. Most dogs need to be kept on amiodarone to maintain sinus rhythm; and the time to relapse to AF may be short in some patients, related to severity of underlying disease, atrial remodeling, and duration of the rhythm (see Chapter 164).

When ventricular tachycardia complicates CHF, the optimal management is often uncertain. Treatment of isolated premature ventricular contractions with antiarrhythmic drugs is not recommended unless an ambulatory (Holter) ECG demonstrates “dangerous” rhythm disturbances at other times. Digoxin is *contraindicated* in the presence of complicated or repetitive ventricular arrhythmias. For management of ventricular tachycardia or dangerous ventricular ectopy, there are both intravenous hospital and long-term drugs. In the hospital lidocaine is the first drug chosen at doses of 2 to 4 mg/kg intravenous boluses up to 8 mg/kg over 10 minutes, followed by a 50- to 75-mcg/kg/minute CRI. Poor hepatic blood flow may lead to accumulation of drug and toxicity at relatively low doses. Procainamide (2 mg/kg boluses up to 10 to 20 mg/kg IV or 10 to 20 mg/kg IM, SQ, PO q6h) and amiodarone (2.5 to 5 mg/kg IV over 10 minutes) are alternatives for life-threatening ventricular tachycardia.

For chronic therapy of ventricular tachycardia, sotalol (1 to 2 mg/kg PO q12h) is best tolerated in dogs not yet in overt CHF, whereas mexiletine (5 to 8 mg/kg PO q8h) seems a better alternative in CHF if adverse effects (gastrointestinal or neurologic) are not severe. In some dogs the combination of mexiletine and low-dose sotalol is more effective. Amiodarone is used increasingly in patients with CHF (10 to 12 mg/kg PO once daily for 2 weeks; thereafter 4 to 6 mg/kg PO once daily). Appetite, history of gastrointestinal signs, liver enzymes/function tests, and complete blood and platelet counts should be followed every 1 to 3 months initially. Either mexiletine or amiodarone can be an effective antiarrhythmic if adverse effects do not supervene. Long-acting procainamide (12 to 20 mg/kg PO q8h) is another but infrequently used alternative.

Chronic (Home) Therapy of Congestive Heart Failure

The transition from hospital to home therapy of CHF may be nearly immediate in mild HF. However, when CHF is severe, a hospitalization period of 24 to 72 hours is typical. During this interval the initial diagnostic workup of thoracic radiographs, serum biochemical profile, ECG, and echocardiogram should be completed. Arterial BP should be measured frequently. Often a follow-up renal and electrolyte panel is obtained before release since vigorous diuretic therapy may alter serum biochemical values. Repeated thoracic radiographs may be obtained to ensure control of the CHF.

The typical transition to home therapy is as follows: (1) parenteral furosemide is replaced with oral furosemide; (2) oxygen is discontinued; (3) nitroglycerin is replaced with an ACE inhibitor (if not already on board); (4) pimobendan therapy is initiated; (5) digoxin is added if needed for rate control in AF; (6) spironolactone is initiated for cardioprotection; (7) the client is counseled regarding a sodium-restricted diet and the pros/cons of nutraceuticals; and (8) in dogs with echocardiographic evidence

of left ventricular systolic dysfunction, carvedilol is prescribed; this therapy begins 2 to 4 weeks after initial CHF treatments and is up-titrated slowly as described previously; (9) in cases of severe pulmonary hypertension sildenafil therapy is discussed with the owner; (10) when AF complicates CHF, diltiazem is usually added to gain better heart rate control.

Most dogs respond well to multidrug treatment of CHF. The essential components of this therapy for confirmed dogs with CHF caused by DVD or DCM are dietary sodium restriction, furosemide, spironolactone, an ACE inhibitor, and pimobendan. These drugs are summarized in the previous section, and this strategy is detailed in Table 171-1. As HF progresses, fine tuning of this regimen is always necessary and should begin with drug dose optimization as discussed previously under management of stage D HF.

Follow-Up and Prognosis

Drug dosing and adverse drug effects are discussed with every client. Written instructions are optimal, including a summary of common adverse drug effects. Follow-up evaluations are rescheduled, emphasizing quality of life factors (eating, sleeping, mild exercise, family interaction, and clinical signs of disease or drug toxicity); home respiratory rate; physical examination findings; changes in body weight; current BP, renal function, and electrolyte values; heart rate and rhythm; and thoracic radiography. Renal function is particularly important to follow since HIF, sodium restriction, diuretic therapy, and ACE inhibitors can lead to an elevation of blood urea nitrogen and creatinine. Many dogs have primary renal disease, putting them at risk for development of azotemia or uremia. Common follow-up intervals are 7 to 14 days after initial diagnosis, 1 month later, and then every 3 months or immediately if problems develop.

COMPLICATING PROBLEMS IN CANINE HEART FAILURE

Severe pulmonary hypertension often occurs in dogs with chronic DVD, leading to exertional problems and ascites. This condition is likely related to elevated left atrial pressure, reactive pulmonary vascular change, and possibly concurrent lung disease. Ascites and pleural effusion are also common when AF develops later in the course of CHF, superimposed on pulmonary hypertension.

Some dogs with chronic left-sided CHF appear to develop pulmonary fibrosis and loud lung crackles at an accelerated rate; this should be recognized and not misdiagnosed as uncontrolled CHF. Dogs with chronic airway disease (tracheal or primary bronchial collapse or chronic bronchitis) may become symptomatic because of these diseases and require empiric courses of antibiotics (we use doxycycline initially) or even brief courses of prednisone at antiinflammatory doses.

Severe dental disease is often present as a comorbid condition in older small-breed dogs with DVD; this oral disease can reduce quality of life. This may require antibiotic therapy (amoxicillin with clavulanate or clindamycin) to reduce periodontal reaction or even a quick dental

Table 171-1

Chronic (Home) Management of the Dog With Congestive Heart Failure

Treatment(s)	Treatment	Comments	Dosages Guidelines
Dietary modifications	Reduce sodium intake; Consider OTC “senior diets” and prescription diets; optimal dosing of nutraceuticals in heart disease is generally not known	Discuss pros and cons of nutraceuticals (limited data; often expensive); consider taurine ± L-carnitine in cocker spaniels, L-carnitine in boxers, L-arginine for dogs receiving sildenafil for pulmonary hypertension; fish oils (EPA, DHA) in dogs with cardiac cachexia or poor appetite	Stringent restriction is <12 mg Na ⁺ /kg of body weight daily; avoid high salt snacks, cheeses, and processed meats (hot dogs) Taurine: 250-500 mg PO q8-12h; L-carnitine: 40-50 mg/kg PO q8-12h; L-arginine: 250-500 mg PO q12h; ω-3 fatty acids: 40-50 mg/kg PO q12h
Furosemide	Prevent chronic sodium retention and edema	Dose to clinical/x-ray effect; follow BUN and BP	Furosemide: 2-6 mg/kg PO one to three times daily
Spironolactone	K ⁺ sparing, low-potency diuretic; cardioprotective	Mainly for heart protection; beware of ↑K ⁺	Spironolactone: ≈2 mg/kg PO once daily or divided BID
Inotropic drugs	Pimobendan (Vetmedin): potent oral inodilator Digoxin: modest inotrope that sensitizes baroreceptors increasing vagal tone	Pimobendan for CHF caused by DVD or DCM; also useful for other causes of canine CHF Digoxin for CHF with atrial fibrillation Digoxin contraindicated in renal failure, complex PVCs or bradycardia	Pimobendan: 0.2 to 0.3 mg/kg PO q12h Digoxin: 0.005 to 0.0075 mg/kg PO q12h
ACE-inhibitor	Enalapril, benazepril, and ramipril are most often used ACE-inhibitors in canine CHF	Maintain systolic BP above 85-90; follow BUN/Cr/K ⁺	Enalapril or Benazepril: 0.25-0.5 mg/kg PO q12h; the “full dose” is prescribed if BUN/Cr and BP are stable after 2 weeks of therapy
β-blocker	Carvedilol is the most often used β-blocker in canine CHF	Patient must be “dry” before beginning therapy Dosage is for dogs with DCM or left ventricular dysfunction; dogs without CHF can tolerate higher doses	Carvedilol: 0.05-0.5 mg/kg PO once or twice daily; start low and up-titrate every 2-4 weeks to target of ≈0.5 to 0.6 mg/kg PO q12h for the dog in CHF
Sildenafil	Phosphodiesterase V inhibitor that maintains the vasodilator effects of the nitric oxide messenger cyclic GMP	Sildenafil and related drugs are relatively specific pulmonary vasodilators used for treatment of severe PH with associated clinical signs	Initial dose is ≈0.5 to 1 mg/kg q8-12h Dosages up to 3 mg/kg q8h may be tolerated
Diltiazem	A calcium channel blocker used for control of heart rate in atrial fibrillation; not a drug treatment for CHF	Negative inotrope and vasodilator drug; can lower BP; initial dose is up-titrated rapidly (daily) to achieve rate control target of 120 to 160/minute at rest during hospital examination	Initial dose ≈0.5 mg/kg PO q8h of standard diltiazem (or 1.5 mg/kg divided BID for long-acting diltiazem); most dogs require total daily dose of 3 to 6 mg/kg

ACE, Angiotensin-converting enzyme; BID, twice a day; BP, blood pressure; BUN, blood urea nitrogen; CHF, congestive heart failure; Cr, creatinine; EPA, eicosapentaenoic acid; DCM, dilated cardiomyopathy; DHA, docosahexanoic acid; DVD, degenerative valvular heart disease; GMP, guanosine 5'-monophosphate; K⁺, potassium ion; NA⁺, sodium ion; PH, pulmonary hypertension; PVC, premature ventricular contraction; OTC, over the counter; PO, orally.

procedure to extract diseased teeth (with attendant risks of anesthesia).

Osteoarthritis is another common comorbid disease in older dogs with HF, especially in the larger breeds. The use of COX inhibitors can be beneficial, but initial doses should be one half of the regular dose, gastric protection (famotidine) should be prescribed daily, and renal function followed. A 4-week course of famotidine is also an empiric treatment for dogs with chronic CHF with recurrent anorexia.

The combination of primary renal failure and CHF is very difficult to manage because they require treatments directly opposed to one another (i.e., fluid repletion versus plasma volume control). When uremic signs develop, euthanasia may be prompted.

PROGNOSIS IN CANINE HEART FAILURE

The prognosis of canine CHF depends on the cause and severity of disease and the overall quality of management. Many dogs survive well beyond 1 year following the first signs of CHF with optimal veterinary and home care. It may take 2 to 4 weeks to obtain optimal stabilization of seriously ill dogs with CHF. Not every patient becomes well overnight, and clients should be so advised. As dogs become well managed, other problems may become evident.

The causes of death in chronic CHF vary but are most often related to one of the following: sudden electrical event (such as asystole or ventricular fibrillation); hypoxemia (pulmonary edema or pleural effusion); pulmonary embolism leading to fatal hypotension; multisystemic

organ failure; or client desire for euthanasia. Client desire for euthanasia is a particularly common ending and depends on many factors that include effectiveness of therapy, severity of signs, client (and veterinarian) perceptions about quality of life, and issues of care (medication frequency, visits to the veterinary hospital, and costs) among other factors. It is important to ensure that clinical signs of disease are not caused by overmedication or drug toxicosis.

CHAPTER 172

Chronic Valvular Disease in Dogs

JOHN E. RUSH, *North Grafton, Massachusetts*

Chronic valvular disease (CVD) is the most common acquired heart disease in dogs, with an overall cumulative incidence of greater than 40%. CVD often results in congestive heart failure (CHF); and cardiac disease is responsible for approximately 10% of all canine deaths, with a higher incidence in some breeds of dogs such as the Cavalier King Charles spaniel. The mitral valve is most commonly affected, but concurrent tricuspid valve disease is often noted. Most veterinarians are very familiar with canine cardiac diseases, particularly CVD; thus the goal of this chapter is to discuss and highlight some important concepts, frequently discussed topics, and exciting diagnostic and therapeutic developments.

ETIOLOGY, PATHOLOGY, AND PATHOPHYSIOLOGY

The cause of CVD is currently unknown, although a genetic tendency to develop the disease has been proven

in the Cavalier King Charles spaniel. As canine genomics develops it is likely that specific genes causing or contributing to the development of CVD will be identified. In addition, poorly defined environmental factors likely play a role in the rate of onset or severity of the disease.

Advanced valvular degeneration leads to grossly thickened and shortened valves with curled, nodular margins. Valvular hemorrhage and calcification may be seen. There is fibrosis of the valves, loss of collagen fibers, and an accumulation of acid-staining glycosaminoglycans within affected valves. Chordae tendineae are often affected and may become thickened, stretched, or ruptured. Electron microscopy has documented great variation in endothelial cell size and morphology of affected valves, with focal loss of the endothelial layer, collagen exposure, and activation of interstitial cells of the valve. It is not clear which of these findings is a result of the disease and which might be a cause or contributor to disease progression. CVD has historically been considered a noninflammatory,

myxomatous degeneration of the atrioventricular valve, but there is growing interest in the role that serotonin or other inflammatory mediators may play in accelerating the pathology of the disease. There is one report of elevated C-reactive protein concentrations in the serum of affected dogs, suggesting a possible role of low-grade systemic inflammation in progression of the disease (Rush et al., 2006). Another study evaluating genomic expression patterns from the valves of dogs with CVD confirmed activation of several pathways involved in cell signaling, inflammation, and extracellular matrix activation, with several inflammatory cytokines and serotonin-transforming growth factor β pathways identified as contributory to the development of the degenerative process in the valve (Oyama and Chittur, 2006). Separate from the valve, many dogs with CVD have histopathologic lesions in the myocardium, including small foci of myocardial fibrosis and necrosis, as well as more widespread intramural coronary arteriosclerosis (Falk et al., 2006). The role that arteriosclerosis, myocardial fibrosis, and microinfarction resulting from occlusion of these arteriosclerotic lesions might play in the progression toward ventricular dilation and CHF is not well understood at this time, but these lesions seem to offer possible alternative avenues for investigation as treatment or interventional opportunities.

Progressive valvular thickening leads to valvular regurgitation and progressive dilation and hypertrophy of the atria and ventricles. Classic compensatory mechanisms (sympathetic nervous system activation, enhanced renin-angiotensin system activity) are activated in an attempt to restore blood pressure and tissue perfusion. As long as the dilated left atrium remains sufficiently compliant to accept the regurgitant blood volume, CHF does not develop, although coughing may develop from left bronchial compression. Eventually, as the volume of regurgitated blood becomes overwhelming, chordal rupture suddenly increases the regurgitant fraction, or the left ventricular myocardium starts to fail, CHF develops. This is typically in the form of pulmonary edema for mitral valve disease. Chronic left heart failure often leads to pulmonary hypertension (PHTN), posing added strain to the right heart and leading to signs of right-sided CHF with accumulation ascites and possibly pleural effusion. Atrial rhythm disturbances, including atrial fibrillation, can contribute to cardiac dysfunction.

Clinical Evaluation of the Dog With Chronic Vascular Disease

CVD is identified most commonly in middle-aged or older, small- to medium-sized breeds of dogs. Although CVD also occurs in large-breed dogs, dilated cardiomyopathy is a more common cause of CHF in these breeds than CVD. When large-breed dogs develop CVD, concurrent myocardial failure is often noted early in the disease. The incidence of CVD is increased in male dogs relative to females (1.5 to 1).

Clinical Presentations in Chronic Vascular Disease

Most dogs are first diagnosed with CVD based on the finding of a cardiac murmur in the absence of any signs of

cardiac decompensation. The period between first identification of a murmur and onset of clinical signs is generally years. As the disease advances, many dogs develop a cough as the first sign of CVD, caused by either early CHF or atrial enlargement causing compression of the airways. Panting, dyspnea, exercise intolerance, weight loss, weakness, and syncope can also be causes for presentation to a veterinarian. Specific triggers that acutely increase fluid volume retention or decrease cardiac performance may precipitate CHF. These include dietary intake of salty foods, vigorous exercise or exertion in the prior 48 hours, recent onset of a rapid tachyarrhythmia, glucocorticoid administration, overzealous fluid therapy, or general anesthesia.

EVALUATION OF THE ASYMPTOMATIC DOG WITH A HEART MURMUR

Many dogs with CVD have an audible murmur for years before the onset of cardiac decompensation and CHF. An extra systolic sound known as a midsystolic “click” is often detected before the onset of this murmur and has been associated with mitral or tricuspid valve prolapse; this is a sign of early CVD. With rare exception, clinically significant CVD is accompanied by a cardiac murmur of medium intensity to loud murmur. Point of maximal murmur intensity is over the left apex with radiation dorsally and to the right in most cases. In most dogs the intensity of the murmur is roughly correlated with the severity of mitral regurgitation (MR) as long as arterial blood pressure is normal.

When a murmur is auscultated in a dog without clinical signs, baseline testing can be offered to the owner and is often helpful for comparison at subsequent examinations. At a minimum the client should be clearly informed of the presence of the murmur and the fact that the disease may ultimately progress to CHF. Baseline testing might include thoracic radiographs to assess for cardiomegaly and/or echocardiography to confirm the diagnosis and help assess cardiac size and function. A blood pressure measurement is indicated to exclude systemic hypertension, which might accelerate progression of MR. If hypertension is identified, an underlying cause such as renal or adrenal disease should be sought.

EVALUATION OF THE DOG WITH SIGNS OF CARDIAC DYSFUNCTION

Once heart failure develops, a range of clinical presentations are possible, related to the degree and duration of valvular dysfunction. In an acute setting clinical signs are usually pulmonary or behavioral in origin and include cough, tachypnea, retching/gagging, nocturnal dyspnea, orthopnea or “reluctance to settle,” and sometimes either excessive “clinginess” or social isolation. Less commonly abdominal distention from ascites may be present, or the client may detect a “racing heart.” Syncope may be the initial sign of heart disease and can occur as a result of significant arrhythmias, secondary to low cardiac output, in association with a vasovagal (reflex-mediated) response, or following a coughing spell (tussive syncope). In my experience syncope is common at the time of the

initial presentation of heart failure, and syncope in this setting likely has a reflex-mediated or vasovagal component. Some dogs exhibit decreased exercise tolerance and weight loss for weeks to months before the onset of CHF, but these are often overlooked and are rarely the causes for presentation to a veterinarian.

Physical Examination

Pulmonary auscultation may reveal loud bronchial sounds that can progress to pulmonary crackles with the onset of alveolar edema. The latter may be particularly prominent over the hilar or caudal lung fields on inspiration. Hepatomegaly and ascites may be evident in dogs with right-sided CHF from advanced mitral disease with PHTN. Jugular venous distention is commonly appreciated in dogs with ascites. Often the femoral pulses are easily palpated and prominent, even at the time of onset of CHF. Irregularities in pulse rate and strength may be noted in association with an arrhythmia. In animals with CHF the heart rate is usually elevated or in the upper normal range, and sinus arrhythmia is typically absent, although this is variable. The ventricular apex beat is hyperdynamic and is progressively shifted caudally from the fifth intercostal space with increasing disease severity. If present, a precordial thrill is also palpable over the apex. There may be a left ventricular heave or apical thrust. There may be other abnormalities since most CVD patients are geriatric; therefore a complete physical examination is warranted.

Thoracic Radiography

Thoracic radiographs are *essential* to the management of CVD. The earliest characteristic findings on thoracic radiographs are mild left ventricular enlargement and left atrial enlargement, which may be best noted as auricular prominence on the dorsoventral (DV) view at the 2 to 3 o'clock location. Left atrial and left ventricular enlargement elevate the trachea and carina on the lateral radiographic projection, with a decrease in the angle between the trachea and the thoracic spine. The left mainstem bronchus may become elevated and compressed in cases of moderate-to-severe left atrial enlargement. There is straightening of the caudal cardiac border and loss of the caudal cardiac waist. Pulmonary venous dilation occurs; this finding may be best appreciated in the cranial lung fields in the lateral view. Distended pulmonary veins (and arteries in severe cases) can also be identified in the caudal lung fields on the dorsoventral or ventrodorsal projections. Early pulmonary edema is seen as a diffuse increase in interstitial density in the hilar or caudal lung fields, progressing to perihilar fluffy densities and air bronchograms with the onset of alveolar edema. Cardiogenic pulmonary edema appears to have a propensity for the right caudal lung fields, and this finding is noted on the DV view. With tricuspid regurgitation (TR) and right-sided or biventricular CHF, the cranial aspect of the trachea may be elevated, and the caudal vena cava increases in size.

Radiograph evaluation is not only useful for monitoring cardiac chamber size and documenting CHF, but it also serves to guide therapy and exclude other disorders.

Pneumonia can develop in an older dog with CVD and CHF; thus in a patient with new signs or a poor response to therapy, infection or other problem such as lung cancer should be considered. Chronic bronchitis is also common in many dogs with CVD and occasionally can be recognized by the presence of severe bronchial patterns or bronchiectasis.

Electrocardiography

Electrocardiographic findings can include evidence of left ventricular hypertrophy, widened P waves of left atrial enlargement (P mitrale), and infrequently P pulmonale (P >0.4 mV). P pulmonale is seen more frequently in dogs with concurrent respiratory disease. ST segment slurring or depression, which may result from myocardial disease, ischemia, or hypoxia, is evident in some dogs with left ventricular hypertrophy. Sinus rhythm or sinus tachycardia is typical of dogs with CVD and CHF. Atrial arrhythmias, especially atrial premature depolarizations, are common. Atrial fibrillation develops in some dogs with marked atrial enlargement. Conversely, ventricular arrhythmias are relatively uncommon in animals with compensated disease, and even in dogs with CHF ventricular ectopy is far less common than with dilated cardiomyopathy.

Echocardiography

Echocardiography is valuable in assessing cardiac changes, although thoracic radiographs are more useful in identifying CHF. Valvular thickening and valvular prolapse into the atria can be appreciated early in the course of disease. With advancing disease the valve becomes progressively thickened, and left atrial and ventricular enlargement is noted. With severe MR the left atrium enlarges disproportionately to the left ventricle. Rupture of a chordae tendineae leads to a flail mitral leaflet with chaotic valve motion and a tip of the leaflet pointing dorsally into the left atrium in systole. Fractional shortening is normal or increased in the early stages of the disease and increases with increasing regurgitant fraction. Fractional shortening returns toward "normal" or becomes diminished with disease progression and the onset of myocardial failure; this finding is often noted early in large-breed dogs. The left ventricular free wall often develops a relatively reduced excursion when compared to the septum (the opposite of normal dogs). Although left atrial size is a better objective measure of severity of chronic MR, Doppler methods also can be used. The location and extent of the regurgitant jet can be mapped using color flow Doppler echocardiography as a crude indicator of disease severity. Additional Doppler methods such as measurement of jet diameter or analysis of the proximal isovelocity area may permit more accurate estimation of the regurgitant flow fraction using color Doppler methods.

Frequently there is evidence of tricuspid valve disease. This can include tricuspid prolapse, valvular thickening, and Doppler evidence of TR. High-velocity TR is a marker for PHTN, which can become very severe in some dogs with CVD. Pericardial effusion is observed occasionally on echocardiography related to right-sided CHF or left atrial tear (see Left Atrial Tear or Splitting later in the chapter).

Biomarkers

Natriuretic peptides, including B-type natriuretic peptide (BNP) and atrial natriuretic peptide, are released in response to ventricular and atrial stretch, and the levels of these peptides increase progressively with the onset of CHF. Studies have documented that these peptides are elevated in dogs with CVD and CHF, with progressive increases as the heart enlarges. Natriuretic peptides hold great promise for early identification of patients at risk of developing CHF and for confirming the diagnosis in those dogs with signs that would be consistent with CHF such as shortness of breath or cough. Natriuretic peptides also may offer some prognostic information, and it remains to be seen whether they can be used to assist in treatment decisions or response to therapy. A commercial assay for canine NT-proBNP has recently become available, and in-house natriuretic peptide testing may be available soon. One issue that requires better definition are the “cutoffs” that prove reliable (both sensitive and specific) for the diagnosis of CHF.

TREATMENT OF CHRONIC VALVULAR HEART DISEASE

The therapy for dogs with CVD includes consideration of the patient with preclinical disease and the dog coughing from bronchial compression, the need for both hospital and home treatment plans for the dog with overt CHF, and the management of additional complications of this disorder.

Management of Asymptomatic Dogs

Treatment of asymptomatic CVD in the dog is controversial. Although angiotensin-converting enzyme (ACE) inhibitors are useful in the treatment of overt CHF, the SVEP trial evaluating the ACE-inhibitor enalapril in asymptomatic cavalier King Charles spaniels failed to show a significant prevention benefit in terms of delaying onset of CHF (Kvart et al., 2002). However, the recently published VETPROOF enalapril trial suggested a possible long-term survival benefit of enalapril in dogs with advanced mitral disease treated before the onset of CHF (Atkins et al, 2007). Clearly more studies are needed before definitive recommendations can be made. In view of these studies most cardiologists do not initiate therapy in small-breed dogs with chronic MR in the absence of significant cardiomegaly. Some clinicians initiate ACE inhibitor therapy in preclinical disease when there is moderate-to-severe heart enlargement or when marked change is observed on serial examinations. However, this therapy is still considered empiric, and there is no unanimity about such treatment.

Aside from the controversy noted previously, there may be some other reasons to consider ACE-inhibition in CVD. For example, in larger-breed dogs with MR, cardioprotective therapy with an ACE-inhibitor and/or β -blocker may be reasonable, especially when there is evidence of volume overload, because progressive left ventricular dysfunction seems more common in this patient group. The dog with left atrial enlargement that is coughing from presumed bronchial compression may benefit from ACE inhibitor therapy (or ACE-inhibitor and low-dose diuretic or cough suppressant).

Dogs with CVD and concurrent systemic hypertension should have their hypertension managed, and ACE inhibitors generally are selected first in this particular setting.

β -Blockers are dangerous in uncontrolled CHF, but there may be a role for these drugs in treated heart failure or asymptomatic disease. There is certainly some enthusiasm for implementation of β -blockers in the preclinical phase of CVD based on extrapolation from research studies. However, clinical studies documenting a clear clinical benefit in dogs with spontaneous CVD are still ongoing, and evidence of benefit is completely lacking in this disease. When prescribed, most cardiologists use carvedilol or metoprolol (see Chapter 171). Again, large-breed dogs with significant CVD may be the best candidates for such myocardial protective strategies.

Severe dietary sodium restriction is not recommended in the asymptomatic stage because of early activation of the renin-angiotensin-aldosterone system. However, client education on avoiding high-sodium diets, treats, and table foods is important. One study evaluating the use of a novel diet for management of dogs with asymptomatic CVD identified a reduction in cardiac size during the 4-week dietary trial, demonstrating the impact of dietary sodium on plasma volume and cardiac size (Freeman, Rush, and Markwell, 2006). Studies that document a clear clinical benefit such as a delay in the onset of CHF or improved survival are lacking; thus firm treatment recommendations cannot be made at this time.

Management of Dogs With Congestive Heart Failure

Once CHF develops, many options are available for patient management (see Chapter 171). The patient with severe pulmonary edema requires diuresis. Oxygen administration and sedation (e.g., butorphanol at 0.1 to 0.2 mg/kg intramuscularly [IM] as needed) are helpful supplements to treating hospitalized patients. Some clinicians use topical 2% nitroglycerin as a venodilator for dogs in the hospital setting, but efficacy data for this approach are lacking. Sodium nitroprusside is useful in life-threatening lung edema caused by ruptured chordae tendineae (see Rupture of the Chordae Tendineae later in the chapter). Once stabilized, most dogs are treated with a combination of oral drugs in the home setting to prevent recurrence of CHF, minimize clinical signs, and prolong life.

Furosemide is the most commonly used diuretic, and the dose is titrated to effect (i.e., to limit clinical signs resulting from fluid accumulation). In patients with severe pulmonary edema intravenous boluses of furosemide are indicated, and some clinicians supplement these with a constant-rate infusion of furosemide. The dose of furosemide required to clear significant edema accumulations and cause the animal to be minimally symptomatic (the desired dose) is often close to that resulting in electrolyte disturbance, dehydration, and the development of prerenal azotemia. Doses of furosemide can vary from 2 mg/kg/day in mild CHF up to 4 to 6 mg/kg every 8 hours in advanced disease. Azotemia and electrolyte imbalance can result from the combined use of ACE inhibitors and diuretics; thus serial monitoring of these parameters is indicated. A baseline evaluation of blood urea nitrogen

(BUN), creatinine, and serum electrolytes should be obtained, with serum chemistry recheck done 5 to 10 days after starting these drugs and 5 to 10 days after any significant dosage adjustment, followed by routine evaluation every 3 to 6 months. ACE inhibitors combined with diuretics may not be well tolerated in some dogs with pre-existing renal disease; careful monitoring of clinical signs (appetite and activity) and more frequent assessment of electrolytes and BUN/creatinine are advisable.

Several clinical trials in dogs with CVD and CHF have demonstrated the clinical benefits of ACE inhibitors in reducing clinical signs or delaying the time until clinical deterioration or death. Drugs such as enalapril or benazepril can be initiated in the hospital or home setting. A full dosage of these drugs is generally considered 0.5 mg/kg orally every 12 hours, but many clinicians initiate therapy at one half that dosage and later increase it at the time of first or subsequent follow-up. Blood pressure and renal function are often used to monitor treatment.

The recent approval of pimobendan (Vetmedin), a calcium sensitizer and phosphodiesterase inhibitor, provides an additional effective drug for management of CHF. The positive inotropic and mixed vasodilator properties of pimobendan result in improved control of CHF and clinical signs of heart failure. Several small clinical trials have documented that pimobendan combined with diuretic therapy is at least as effective as furosemide and ACE inhibitors and may have fewer side effects than many of the commonly used cardiovascular medications (Smith et al., 2005). Pimobendan does not appear to have proarrhythmic properties at commonly used clinical doses, but this requires more study. Cardiologists hold some differing opinions on the role that pimobendan plays in the management of CHF in dogs with CVD. Some believe that initial management of CHF should revolve around furosemide and pimobendan, whereas others opt for furosemide with an ACE-inhibitor. I believe that the initial treatment strategy for dogs with CVD and well-defined CHF should include the "triple therapy" of furosemide, pimobendan, and an ACE inhibitor.

As cardiac disease progresses, additional medications will be required to control advancing CHF. This therapy may include a dose escalation of furosemide, the addition of other diuretics to combat diuretic resistance, treatment with digoxin or antiarrhythmics as necessary, and various dietary manipulations. I usually consider that diuretic resistance has developed when doses of furosemide in excess of 2.2 mg/kg twice a day are required to control congestive signs during chronic CHF therapy. In this situation the addition of spironolactone (1 to 2 mg/kg orally [PO] once or twice daily) or a combination of hydrochlorothiazide with spironolactone is recommended. If hydrochlorothiazide is prescribed, initial dosages should be conservative, and renal function and electrolytes should be evaluated within 5 to 7 days. In addition, careful scrutiny of other causes of fluid retention such as high-sodium diets, salty treats, or glucocorticoid therapy is indicated.

Digoxin still has some role in the management of CVD, although it has largely been supplanted by newer drugs with fewer side effects. Digoxin is indicated in CVD dogs in the setting of CHF with atrial fibrillation and in cases with frequent or sustained supraventricular arrhythmias. In addition, digoxin may be useful in management of

syncope in dogs with CVD when no clear cause for collapse (such as arrhythmia) can be established. Toxicity in veterinary patients has the very real potential to contribute to a decision for euthanasia, and the narrow therapeutic window for digitalis glycosides predisposes to the development of toxicity. Serial monitoring of serum digoxin levels is advisable, with target 8-hour postpill serum concentrations in the 0.8- to 1.2-mg/ml range. For dogs with rapid ventricular rate response to atrial fibrillation, either diltiazem or a β -blocker may be required in addition to digoxin to reduce the heart rate to less than 160 beats/min.

β -Blockade has gained favor recently as a therapeutic modality for treatment of CHF. Several studies on the use of β -blockers have documented benefits that accrue from chronic treatment in people with CHF, although these effects often are not seen for several months. Reported benefits include up-regulation of previously down-regulated β -receptors, improved cardiac performance (improved stroke volume), and improved survival. These clinical benefits appear to have sound theoretic basis, but there is not consensus among cardiologists about the use of β -blockers in dogs with CVD. Currently carvedilol is under evaluation in veterinary patients with naturally occurring CHF caused by both cardiomyopathy and CVD. Since β -blockers are negative inotropes, the most demonstrable effect when used in dogs with active CHF is likely to be a worsening of CHF. The negative inotropic and chronotropic effects of β -blockers can be harmful to dogs with active failure or those at the edge of compensation. β -Blockers are best used in patients that are minimally symptomatic with early/mild heart failure or in later stages of CHF that are already well controlled on a stable cardiac drug regimen (see Chapter 171 for more details). Carvedilol, metoprolol, and atenolol all have been used for cardioprotection in dogs with CVD, but carvedilol may have some advantages in terms of concurrent α -blockade (lowering vascular resistance), potent antioxidant effects, and more convenient dosing formulations.

Dietary sodium restriction is also important for the management of dogs with CVD. The owners of an asymptomatic dog with CVD should be counseled to avoid diets high in sodium and to avoid treats or table food (and any foods used to administer medications) that are high in sodium. Initially the selected diet should have a sodium content of less than 100 mg/100 kcal of energy. Once CHF develops, additional sodium restriction is recommended (<80 mg/100 kcal). This does not necessarily require a commercial cardiac diet, and care should be taken to avoid diets designed for dogs with renal disease or cardiac diets that are low in protein since these can contribute to loss of muscle mass and cardiac cachexia. As CHF progresses, stricter dietary sodium restriction may allow for use of lower dosages of diuretics to control clinical signs. A variety of other dietary considerations may be important in individual cases. Some diets are designed or supplemented with various levels of certain nutrients such as potassium, magnesium, taurine, L-carnitine, arginine, antioxidants, or ω -3 fatty acids (see Chapter 157).

Exercise restriction with severe CHF is essential; however, limited exercise in dogs with stable chronic heart failure is often well tolerated and improves quality of life scores. Repetitive or strenuous activities such as ball chasing and running should be restricted once advanced heart disease or serious arrhythmias develop.

CLINICAL COMPLICATIONS AND CHALLENGES

Cough in the Dog With Concurrent Chronic Valvular Disease and Respiratory Disease

The cause of the cough can be difficult to determine in dogs with concurrent cardiac and respiratory disease. Dogs coughing from primary pulmonary disease often are overweight or have no history of weight loss, and auscultation may indicate only a soft murmur or no murmur at all. Many dogs with tracheobronchial disease demonstrate tracheal sensitivity, a very productive cough, or a cough of long-standing duration (often longer than 2 to 4 months). In contrast, most dogs with a cardiac cough have a loud murmur, some weight loss, and a cough of more recent onset. Sinus arrhythmia is more common in the dog with respiratory disease; whereas the dog with CHF often has normal sinus rhythm, sinus tachycardia, or atrial arrhythmias. Both CHF and respiratory diseases such as chronic bronchitis and pulmonary fibrosis can cause crackles and wheezes on auscultation; thus this is rarely a helpful discriminating factor. The radiographic finding of pulmonary edema with interstitial-to-alveolar infiltrates in the perihilar regions, pulmonary venous prominence, and an enlarged left atrium supports a diagnosis of CHF. Marked left atrial enlargement may compress the main-stem bronchi and lead to cough; this cough often improves with therapy for heart failure, which results in a decrease in the size of the left atrium. Dogs with more respiratory findings often have right heart enlargement and a lack of left atrial enlargement on thoracic radiographs.

Rupture of the Chordae Tendineae

Acute rupture of a chordae tendineae may lead to catastrophic heart failure and may be clinically appreciated by a marked change in the murmur intensity and sudden-onset pulmonary edema. Acute CHF develops as the left atrium is unable to compensate for an acute increase in regurgitant volume. Historically chordal rupture has been associated with a grave prognosis. However, a recent review (Serres et al., 2007) concluded that survival time of affected dogs was longer than previously described, with 58% of affected and aggressively treated dogs surviving more than 1 year after diagnosis. Although cardiologists do not always agree on the echocardiographic criteria used in this study for diagnosis of ruptured chordae tendineae, these data suggest that not all chordal ruptures are lethal and that it is reasonable to undertake therapy. In addition to aggressive diuresis, oxygen therapy, and sedation as required, the use of sodium nitroprusside infusion at a rate of 1 to 5 mcg/kg/minute for 24 to 48 hours can be successful in acute load reduction and management of catastrophic heart failure and severe pulmonary edema in dogs with CVD. The dose of nitroprusside is generally titrated to a systolic blood pressure of ≈ 90 mm Hg.

Left Atrial Tear or Splitting

Left atrial tear can result from atrial stretch from MR or from endocardial damage caused by the jet of blood chronically impinging on the endocardial aspect of the left atrium. The weakened endocardium can split; and at times the entire left atrial wall ruptures, allowing blood to escape into the

pericardial sac. The resultant cardiac tamponade may be fatal. The tear may more accurately be characterized as endocardial splitting since this process may occur without rupture of the atrial wall, or rupture may occur without pericardial bleeding (e.g., rupture in the atrial septum leads to an acquired atrial septal defect). Treatment of left atrial tear is directed at aggressively lowering left atrial pressure through treatment of volume overload. Pericardiocentesis is rarely indicated unless tamponade is life-threatening. The volume of blood identified by echocardiography may be relatively small; and great care should be used when tapping the pericardium, especially from the left side, because the dilated left auricle is easily punctured.

Pulmonary Hypertension

PHTN is defined as a resting mean pulmonary arterial pressure of greater than 25 mm Hg. Pulmonary hypertension may occur as an isolated entity, secondary to pulmonary thromboembolism or chronic respiratory disease, or as a result of long-standing left-sided CHF. PHTN often leads to syncope and signs of right-sided CHF such as ascites or even pleural effusion. PHTN is most often diagnosed by noninvasive continuous-wave Doppler echocardiography with application of the Bernoulli equation to the tricuspid regurgitant jet velocity:

$$\text{PA pressure} = \text{peak velocity}^2 \times 4 \\ + \text{estimated right atrial pressure}$$

where velocity units are in meters per second. Moderate PHTN is common in advanced CVD and can be well tolerated, but severe PHTN is generally associated with a poor prognosis. Pimobendan may reduce pulmonary artery pressures in selected cases. Recently sildenafil (Viagra, Revatio) and tadalafil (Cialis) have been described as a therapeutic option in both humans and dogs with PHTN. I currently add sildenafil or tadalafil to the treatment regimen of dogs with CVD and severe PHTN (estimated systolic pulmonary artery pressures >80 mm Hg) and to those with moderate PHTN (estimated systolic pulmonary artery pressures between 50 and 80 mm Hg) and unresolved syncope or tachypnea following resolution of radiographic evidence of pulmonary edema. It is important to recall that concurrent sildenafil and nitrate therapy is contraindicated because of the potential for severe hypotension. Currently the extralabel prescription of these drugs in most countries is quite expensive.

Surgical Intervention in Chronic Valvular Disease

Surgical procedures have been developed to repair or replace the mitral valve in dogs with CVD. Cardiopulmonary bypass is required for these procedures; successful cardiopulmonary bypass requires a dedicated team of surgeons, perfusionists, anesthesiologists, cardiologists, intensive care specialists, and strong veterinary technician support. The cost associated with surgery can be prohibitive (\$8,000 to \$12,000). Once these techniques are mastered and refined for veterinary medicine, it seems probable that surgery or developing catheter-based interventions (or hybrid procedures) to limit MR will become the preferred treatment for those that can afford the procedure.

CHAPTER 173

Infective Endocarditis

KRISTIN A. MACDONALD, *Davis, California*

Infective endocarditis (IE) is an uncommon, often deadly, and sometimes difficult to diagnose disease in veterinary medicine. IE is caused by invasion of a microbe into the endothelium of the valves of the heart, resulting in proliferative or erosive lesions and consequently valvular insufficiency. The incidence of IE in dogs referred to a veterinary teaching hospital is low (0.09% to 6.6%) (MacDonald et al., 2004; Calvert, 1982). Given the difficulty in diagnosis, the nebulous clinical signs, and lack of necropsy examinations, the true incidence of IE in the canine population is likely much higher. IE in cats is extremely rare. In small animals the mitral and aortic valves are almost exclusively affected with nearly equal distribution. Patients often succumb to congestive heart failure (CHF), sudden death, or thromboembolic disease. Immune-mediated diseases, including polyarthritis or glomerulonephritis, are also common secondary sequelae. Identification of the offending organism is paramount for effective treatment with long-term antibiotics. Blood culture is especially helpful to identify the offending organism and determine the spectrum of antibiotic sensitivity. However, the incidence of culture-negative IE in dogs is high at 60% to 70% (MacDonald et al., 2004; Sisson and Thomas, 1984). This update considers IE in the dog and discusses the emergence of *Bartonella* as a cause

of IE in dogs with blood culture negative for traditional bacteria. Recent advances in diagnosis, treatment, and prognosis of IE in dogs are also reviewed.

PREDISPOSING FACTORS

Bacteremia of any cause may predispose a patient to develop IE. Common sources of bacteremia include discospondylitis, prostatitis, pneumonia, urinary tract infection, pyoderma, periodontal disease, and long-term indwelling central venous catheters. Subaortic stenosis is the only structural heart disease that significantly predisposes dogs to development of aortic valve IE (Sisson and Thomas, 1984). Dogs with myxomatous valvular degeneration rarely develop IE despite dental prophylaxis procedures and other causes of bacteremia and therefore are not likely to have a substantially increased risk for development of IE. The role of immunosuppressive therapy (i.e., corticosteroids) as a predisposing factor for development of IE is controversial. In a recent study of IE in dogs only 1 of 18 dogs (5%) had been recently administered immunosuppressive therapy for treatment of pemphigus foliaceus. However, an earlier study found that 17 of 45 dogs (38%) with IE received corticosteroids at some time during the course of disease (Calvert, 1982).

PATHOPHYSIOLOGY

Vegetative Lesions

The inciting event in formation of IE is bacterial adherence to the disrupted endothelial surface of a cardiac valve. Mechanical lesions (i.e., subaortic stenosis or cardiac catheterization procedure) or inflammatory disease can promote bacterial seeding within the endothelium. During disruption of the endothelium, extracellular matrix proteins, thromboplastin, and tissue factor all trigger coagulation; and a coagulum forms on the damaged endothelium. This coagulum contains fibrinogen, fibrin, and platelet proteins and avidly binds bacteria. Inflammation induces endothelial cell expression of integrins that bind bacteria and fibronectin to the extracellular matrix. Some bacteria (i.e., *Staphylococcus aureus*) carry fibronectin-binding proteins and also can trigger active internalization by host cells. Organisms that commonly cause IE are those that have the greatest ability to adhere to damaged valves and include *Staphylococcus* spp. and *Streptococcus* spp. These bacteria can trigger tissue factor production and induce platelet aggregation. Platelets release bactericidal proteins, but many of the bacteria that cause IE are resistant to these proteins. Bacteria such as *S. aureus* and *Bartonella* may become internalized within the endothelial cells and escape detection by the immune system. *Bartonella* also evade the immune system by colonizing red blood cells without causing hemolysis. Bacteria also can excrete enzymes that lead to destruction of valve tissue and proliferation of the vegetative lesion. The fibrinous vegetative lesion shields bacteria from the bloodstream and inflammatory cells and provides a formidable obstacle for antibiotic penetration.

Congestive Heart Failure

CHF generally develops subsequent to severe aortic or mitral insufficiency in dogs with IE of those valves. Rarely vegetation also creates stenosis of the valve. Increased left ventricular end-diastolic pressure occurs secondary to severe valvular insufficiency and leads to elevated left atrial and pulmonary capillary wedge pressures with development of cardiogenic pulmonary edema.

Immune-Mediated Disease

Patients with IE tend to develop high titers of antibodies against causative microorganisms, and there is continuous formation of circulating immune complexes. Subacute IE in humans is more likely to result in immunologic disease (Baddour et al., 2005). Immune complexes consist of immunoglobulin (Ig)M and IgG, as well as C3 (complement). Factors such as rheumatoid factor may impair the ability of complement to solubilize immune complexes and may lead to formation of large immune complexes. Extracardiac disease manifestations are caused by immune complex deposition and further complement activation and tissue destruction in the glomerular basement membrane, joint capsule, or dermis. Circulating immune complexes are greatly reduced shortly after antibiotic therapy in humans with IE.

CLINICAL PRESENTATION

Medium- to large-breed, middle age-to-older male dogs are most commonly affected with IE. German shepherds were predisposed to develop IE in a postmortem study. In a recent study the most frequent presenting complaint of dogs with IE was lameness (44% of dogs), followed by nonspecific signs such as lethargy, anorexia, respiratory abnormalities, weakness, and collapse (MacDonald et al., 2004). Some dogs exhibit signs that suggest fever such as shaking or shivering.

Cardiopulmonary Abnormalities

A murmur is ausculted in a majority of dogs with IE (89% to 96%) (MacDonald et al., 2004; Sisson and Thomas, 1984). Clinical findings of a diastolic murmur and bounding femoral pulses should trigger a high level of suspicion of aortic valve IE, and further diagnostics should be pursued immediately as outlined in the following paragraphs. Fever is often present (50% to 74%). Arrhythmias are present in 40% to 70% of dogs and include in order of incidence ventricular arrhythmias, supraventricular tachycardia, third-degree atrioventricular block, and atrial fibrillation. The highest reported frequency of arrhythmias was seen in dogs with aortic IE, with 62% of dogs having ventricular arrhythmias (Sisson and Thomas, 1984). Third-degree atrioventricular block may occur with periannular abscess formation secondary to aortic valve IE. CHF is present in almost half of patients and is diagnosed by identification of perihilar to caudodorsal pulmonary infiltrates. Acute CHF occurs in the absence of significant left atrial enlargement in a majority of cases of IE (75%) (MacDonald et al., 2004). There is no difference in the occurrence of CHF between IE of the mitral or aortic valves.

Other Systemic Sequelae

Thromboembolism (septic and aseptic) commonly occurs in 70% to 80% of dogs with IE examined in the pathology table (MacDonald et al., 2004). Risk of thromboembolic disease is greatest with vegetative lesions larger than 1 cm in size or with increasing lesion size during antibiotic therapy in people. Infarction of the kidneys and spleen is most common in dogs, followed by myocardium, brain, and systemic arteries.

Immune-mediated disease, including polyarthritis and glomerulonephritis, is commonly seen in dogs with IE (6 of 8 or 75% and 4 of 11 or 36%, respectively, in our study). Joint fluid analysis and culture should be performed in any dog with lameness. Urine protein:creatinine ratio should be evaluated in any dog with proteinuria to support the diagnosis of glomerulonephritis.

Clinicopathologic Abnormalities

Complete blood count commonly reveals leukocytosis (78%) with a mature neutrophilia and monocytosis. Mild-to-severe thrombocytopenia is commonly seen in over half of all cases. Mild nonregenerative anemia is also commonly seen. Serum chemistry may show hypoalbuminemia, elevated hepatic enzyme activity, and acidosis.

Azotemia may be prerenal or renal. Renal infarction may be seen secondary to thromboembolic disease in IE and may cause severe azotemia. Urinalysis commonly reveals hemoglobinuria, hematuria, proteinuria, and cystitis. Urine culture should be obtained in all cases in an effort to identify possible offending microbes.

DIAGNOSIS

Blood Culture

Blood culture before treatment with antibiotics is an essential tool to support the diagnosis of IE and to aid in proper selection of antimicrobial treatment. Unfortunately many patients (78% in one study) have been treated with antibiotics before blood culture, thus reducing the likelihood of a positive blood culture. Three or four blood samples (5 to 10 ml) should be collected aseptically from different venous sites at least 30 minutes to 1 hour apart and submitted for aerobic and anaerobic culture. Lysis centrifugation tubes (Isolator, Isostat microbial system, Wampole

Laboratories) may increase diagnostic yield. For culture of *Bartonella*, a fastidious gram-negative intracellular bacterium, 2 ml of aseptically collected blood is placed in a plastic tube containing ethylenediaminetetraacetic acid (EDTA) (K₂EDTA blood tubes, Becton Dickinson VACUTAINER Systems) and frozen at -70° C until plated. Samples are plated on specialized culture medium of heart infusion agar and incubated in 5% CO₂ for up to 4 weeks.

Bacterial Isolates

There is a high incidence of negative blood cultures in dogs with IE ranging from 60% to 70% (MacDonald et al., 2004; Sisson and Thomas, 1984). The most common bacterial isolates are *Staphylococcal* spp. (*S. aureus*, *S. intermedius*, coagulase-positive, and coagulase-negative), *Streptococcus* spp. (*S. canis*, *S. bovis*, and β -hemolytic), and *Escherichia coli* (Table 173-1). Other isolates cultured in our teaching hospital and reported in other case series include

Table 173-1

Common Etiologic Agents, Typical Antimicrobial Sensitivity Profiles, and Treatment Recommendations for Dogs With Infective Endocarditis

Etiologic Agent	Typical Sensitivity Profile	Recommended Antibiotic
<i>Staphylococcus intermedius</i>	Usually sensitive	Acute: Timentin 50 mg/kg IV QID, or enrofloxacin 10 mg/kg IV BID, or amikacin 20 mg/kg IV q24h, with fluid support Chronic: Clavamox 20 mg/kg PO TID, or enrofloxacin 5-10 mg/kg PO BID \times 6-8 weeks Individually dependent, evaluate MIC
<i>Staphylococcus aureus</i>	Often resistant If methicillin resistance, avoidance of β -lactams	Acute: May require amikacin or vancomycin, and oxacillin, nafcillin, or cefazolin IV \times 2 weeks Chronic: If not methicillin resistant, high-dose first-generation cephalosporin PO 6-8 weeks
<i>Streptococcus canis</i>	Usually sensitive If resistant, amikacin and high-dose penicillin	Acute: Ampicillin 20-40 mg/kg IV TID-QID, or ceftriaxone 20 mg/kg IV BID \times 2 weeks Chronic: Amoxicillin or Clavamox PO 6-8 weeks Individually dependent, evaluate MIC
<i>Escherichia coli</i>	Often resistant because of β -lactamase, need extended MIC	Acute: Amikacin and/or imipenem 10 mg/kg IV TID Chronic: Imipenem 10 mg/kg SQ TID 6-8 weeks Individually dependent, evaluate MIC
<i>Pseudomonas</i>	Resistant, need extended MIC	Acute: Amikacin, Timentin, or imipenem IV Chronic: Imipenem SQ or possibly Clavamox PO
<i>Bartonella</i>	MIC not predictive of MBC	Acute: Amikacin 20 mg/kg IV \times 1-2 weeks, and β -lactam (i.e., Timentin 50 mg/kg IV QID \times 1-2 weeks) Chronic: β -lactam PO \times 6-8 weeks Doxycycline 5 mg/kg PO q24h \times 6-8 weeks Azithromycin 5 mg/kg PO q24h \times 7 days and then EOD
Unknown etiologic agent	Culture negative	Acute: Amikacin and Timentin IV \times 1-2 weeks Chronic: Clavamox 20 mg/kg TID \times 6-8 weeks and Enrofloxacin 5-10 mg/kg PO BID \times 6-8 weeks

Typical MIC profiles derived from University of California Davis Veterinary Medical Teaching Hospital's microbial service database of antimicrobial sensitivity of cultured microorganisms. Recommended antibiotics for particular bacteria were chosen based on >90% of the cultured isolates sensitive to the particular antibiotic. BID, Twice a day; EOD, every other day; IV, intravenously; MBC, minimum bactericidal concentration; MIC, minimum inhibitory concentration; PO, orally; QID, four times a day; SQ, subcutaneously; TID, three times a day.

Pseudomonas spp., *Erysipelothrix rhusiopathiae*, *Enterobacter* spp., *Pasteurella* spp., *Corynebacterium* spp., and *Proteus* spp. Rare bacterial isolates include *Bordetella avium*-like organism, *Erysipelothrix tonsillarum*, and *Actinomyces turicensis*.

***Bartonella* Infective Endocarditis**

Bartonella has emerged as an important cause of culture-negative IE in humans and dogs (Houpikian and Raoult, 2005; MacDonald et al., 2004). *Bartonella* was the cause of 28% of IE in dogs in a recent study and of IE in 45% of dogs with negative blood cultures. *Bartonella vinsonii berkhoffii* is the most common species to cause IE in dogs, followed by *B. henselae*, *B. clarridgeiae*, *B. "clarridgeiae-like"*, and *B. washoensis*. *Bartonella* primarily affects the aortic valve and less commonly affects the mitral valve in dogs. *Bartonella* causes unique valvular lesions characterized by fibrosis, mineralization, endothelial proliferation, and neovascularization (Pesavento et al., 2005). *Bartonella* evades the immune system by colonizing red blood cells and endothelial cells and also impairs the immune system by reducing the number of CD8+ lymphocytes and their cell adhesion molecule expression, inhibiting monocyte phagocytosis, and impairing B cell antigen presentation within lymph nodes (Pappalardo et al., 2001). The clinical characteristics of dogs with IE caused by *Bartonella* are not different from those of dogs with IE caused by traditional bacteria. Despite the use of specialized culture medium and long incubation periods, *Bartonella* is rarely cultured from the blood of dogs with IE. Dogs with polymerase chain reaction (PCR)-confirmed IE caused by *Bartonella* were highly seroreactive to *Bartonella* spp., and titers were higher than 1:1024 in one study (MacDonald et al., 2004). There is cross-reactivity to different *Bartonella* spp., as well as to *Chlamydia* spp. and *Coxiella burnetii*. PCR of the infected valve or possibly blood may be useful to confirm a diagnosis of *Bartonella*. In my experience dogs with IE caused by traditional bacteria do not have coinfections with *Bartonella* (MacDonald et al., 2004; Pesavento, 2005). Several epidemiologic studies have suggested that ticks and fleas may be vectors for *Bartonella*. Concurrent seroreactivity to *Anaplasma phagocytophilum*, *Ehrlichia canis*, or *Rickettsia rickettsii* is common in dogs with IE caused by *Bartonella*, and titers should be submitted for tick-borne diseases in any dog that is seroreactive to *Bartonella* antigen (MacDonald et al., 2004; Breitschwerdt et al., 1998).

Echocardiography

Diagnosis of IE in dogs relies primarily on visualization of a characteristic vegetative lesion of the valve by echocardiography (ECHO). Vegetative lesions appear hyperechoic and oscillating and move independently from the valve. Smaller lesions may be most obvious on the valvular surface facing blood flow. Chronic lesions may appear hyperechoic or rarely calcified. The mitral and aortic valves are almost exclusively affected in small animals. Severe proliferative myxomatous valve degeneration must be differentiated from vegetative lesions. Patient signalment is often helpful since dogs with marked myxomatous mitral valve

degeneration are small breeds that rarely develop IE and dogs with IE are medium to large breeds that do not commonly develop marked valvular thickening as a result of myxomatous valve degeneration. In humans transthoracic ECHO has a low sensitivity of 55% for detection of vegetative valvular lesions compared to transesophageal ECHO (Reynolds et al., 2003). Although no veterinary study has compared the sensitivity of transthoracic ECHO versus transesophageal ECHO, the sensitivity of transthoracic ECHO is likely higher given the smaller size of our veterinary patients and the adequate visualization of the mitral and aortic valves in most dogs. Erosive lesions may be more difficult to identify. Presence of moderate or severe aortic insufficiency on color flow Doppler should greatly raise the suspicion of aortic IE, and careful interrogation of the aortic cusps in several views may be necessary to identify the vegetation. Subaortic stenosis may be present and can be diagnosed by two-dimensional evidence of fibrotic narrowing of the left ventricular outflow tract, and severity can be determined by measurement of aortic blood flow velocity by continuous-wave Doppler using the left apical five-chamber view. Severity of aortic insufficiency may be estimated by the width of the jet origin, possibly by the length of the insufficiency jet on color flow Doppler, and by the slope of the aortic insufficiency on continuous-wave Doppler (i.e., steep slope, severe aortic insufficiency). Mitral regurgitation may occur secondary to vegetative or erosive mitral lesions. Left atrial enlargement or eccentric hypertrophy of the left ventricle may not be present if the IE is acute in nature. If there is a high clinical suspicion of IE (new valvular insufficiency, fever, polyarthritis, leukocytosis, bacteremia) and no vegetative lesions are seen by transthoracic ECHO, transesophageal ECHO is recommended to better evaluate the mitral and aortic valves.

Suggested Criteria for Diagnosis of Infective Endocarditis

Definitive diagnosis of IE depends on identification of a vegetative or erosive lesion by ECHO or pathology. The modified Duke criteria have been developed to identify humans at high risk for IE and have been further modified for use in dogs evaluated for possible IE (Box 173-2). Since transthoracic ECHO is relatively insensitive in humans for detection of IE, other major and minor criteria are used to determine a possible diagnosis (Baddour et al., 2005). Cases of possible IE with high clinical suspicion should undergo transesophageal ECHO to better evaluate the valve morphology, or transthoracic ECHO should be repeated in a few days. Specific serologic data (*Coxiella burnetii* IgG titer >1:800) have recently been added to the Duke criteria to identify an etiologic agent in culture-negative cases in humans. Based on the veterinary literature, high seroreactivity to *Bartonella* (>1:1024) may be an additional minor criterion for diagnosis of IE caused by *Bartonella* in dogs. A titer of greater than 1:800 for IgG antibodies to *B. henselae* or *B. quintana* had a positive predictive value of 0.96 for detection of *Bartonella* infection in humans with IE and confirmed the diagnosis in 45 of 145 humans (31%) with culture negative IE with 100% sensitivity (Fournier et al., 2002). PCR on serum from humans with confirmed

Box 173-1

Suggested Criteria for Diagnosis of Infective Endocarditis in Dogs**Major Criteria**

- Positive echocardiogram
- Vegetative, oscillating lesion
- Erosive lesion
- Abscess
- New valvular insufficiency
- >Mild AI in absence of subaortic stenosis or annuloaortic ectasia
- Positive blood culture
- >2 positive blood cultures
- >3 with common skin contaminant

Minor Criteria

- Fever
- Medium to large dog (>15 kg)
- Subaortic stenosis
- Thromboembolic disease
- Immune mediated disease
- Polyarthritis
- Glomerulonephritis
- Positive blood culture not meeting major criteria
- **Bartonella* serology >1:1024
- No pathologic evidence

Diagnosis**Definite**

- Pathology of valve
- Two major criteria
- 1 major and 2 minor

Possible

- 1 major and 1 minor
- 3 minor

Rejected

- Firm alternative Dx
- Resolution <4 days of Rx

AI, Aortic insufficiency; Dx, diagnosis; Rx, treatment.

*Proposed minor criterion in dogs; not officially accepted as criterion. Veterinary criteria are modified from the modified Duke criteria used in human medicine for diagnosis of infective endocarditis.

IE caused by *Bartonella* is relatively insensitive (58%) but specific (100%) (Zeaiter et al., 2003).

TREATMENT

Long-term bactericidal antibiotics are the cornerstone of therapy for IE. Common etiologic agents, their typical sensitivity profile, and therapeutic regimens are included in Table 173-1. Therapeutic recommendations were derived from the University of California Davis Veterinary Medical Teaching Hospital's microbial service database of antimicrobial sensitivity of microorganisms. Recommended antibiotics for particular bacteria were chosen based on greater than 90% of the cultured

isolates sensitive to the particular antibiotic. However, general antibiotic sensitivities and resistance profiles may vary, depending on the hospital. Hospital-acquired infections may be much more resistant than infections acquired within the community. High serum concentration of antibiotics with good tissue and intracellular penetrating properties is needed to enter the vegetative lesion and kill the bacteria. The optimal antibiotic treatment depends on culture of the microorganism and minimum inhibitory concentration (MIC) of the antibiotics. While the culture results are pending or if there is no known microbial etiology, empiric treatment with broad-spectrum antibiotics is recommended, including aminoglycosides and β -lactam antibiotics. There is significant resistance of many bacteria isolated from our hospital to enrofloxacin; therefore it cannot be recommended as an empiric, acute first line of defense when an MIC is unavailable. Patients should be supported with fluid therapy while being treated with aminoglycosides, and concurrent administration of furosemide is contraindicated because it worsens nephrotoxicity. This limits the use of aminoglycosides to patients that are not in CHF. Initial intravenous antibiotic therapy for 1 to 2 weeks is recommended for aggressive therapy, followed by long-term oral antibiotic therapy for 6 to 8 weeks or longer. Subcutaneous administration of antibiotics on an outpatient basis rather than oral antibiotics has been suggested by some clinicians, but there is no clear advantage over chronic oral treatment. One exception is in the chronic treatment of resistant infections using imipenem administered subcutaneously after an initial 1- to 2-week course administered intravenously (Barker et al., 2003). Subcutaneous administration of antibiotics often requires frequent daily injections, and client compliance may be suboptimal. In addition, bioavailability of oral antibiotics such as the β -lactams (i.e., amoxicillin and Clavamox) and fluoroquinolones is very high (>75%, >90%, >90%, respectively). According to the resistance profiles of bacteria cultured from patients within our hospital, many bacteria are resistant to ampicillin, and empiric use of ampicillin cannot be recommended without an MIC.

The treatment of choice for *Bartonella* infections has not been defined in human or veterinary medicine. MICs are not indicative of therapeutic efficacy of antibiotics against intracellular bacteria, including *Bartonella*, and minimum bactericidal concentration may be more appropriate. In an in vitro study only gentamicin and not ciprofloxacin, streptomycin, erythromycin, ampicillin, or doxycycline exerted bactericidal activity against *Bartonella* (Rolain et al., 2000). Treatment with at least 2 weeks of aminoglycosides has been shown to improve survival in humans with *Bartonella* IE (Raoult et al., 2003). Current treatment recommendations in humans include aminoglycosides and β -lactam antibiotics for 4 to 6 weeks (Baddour et al., 2005). In 24 dogs with various systemic manifestations secondary to bartonellosis, treatment with the following antibiotics resulted in clinical recovery and negative post-treatment titers: doxycycline, azithromycin, enrofloxacin, and amoxicillin/clavulanate (Breitschwerdt et al., 2004). In dogs with severe life-threatening IE caused by *Bartonella*, aggressive treatment with aminoglycosides

may be necessary, with careful monitoring of renal enzymes and supportive intravenous fluid administration. Azithromycin achieves high intracellular concentrations and may be given with careful monitoring of the hepatic enzymes since it may cause hepatotoxicity with chronic therapy.

Anticoagulant therapy is not currently recommended since there has been a trend of increased bleeding episodes and no benefit in vegetation resolution or reduced embolic events in humans with IE treated with aspirin (Baddour et al., 2005).

Treatment of CHF

Dogs with CHF should be treated with furosemide at the appropriate dose, depending on severity of pulmonary edema (stable mild-to-moderate CHF, 1 to 4 mg/kg orally [PO] BID-TID; acute fulminant CHF, 5 to 8 mg/kg intravenously [IV] q 2–4h initially and then reduced according to patient's response). In dogs with significant aortic insufficiency secondary to aortic IE or massive mitral regurgitation, afterload reduction using amlodipine, hydralazine, or nitroprusside should be instituted providing the dog is not hypotensive at baseline. Aggressive afterload reduction in hypertensive patients is warranted. In normotensive animals the target reduction of blood pressure from baseline is 10 to 15 mm Hg. Adjunctive therapy for chronic CHF includes an angiotensin-converting enzyme inhibitor and possibly digoxin if there is myocardial failure (see Chapter 171). Antiarrhythmic treatment may be necessary, especially if there are high-grade ventricular arrhythmias (see Chapter 162).

Follow-up

In patients with initially positive cultures (blood or urine), repeat culture is recommended 1 to 2 weeks after starting antibiotic therapy and 2 weeks following termination of antibiotic therapy. An echocardiogram should be performed after 2 weeks of antibiotic treatment, in 4 to 6 weeks, and 2 weeks following termination of antibiotic therapy to assess size of vegetative lesion and severity of valvular insufficiency. In patients affected with *Bartonella*, repeat serology should be performed a month after initiation of treatment, and titers should be reduced. If titers are elevated persistently, a different antibiotic may be needed.

Prophylaxis

In dogs with congenital heart disease, in particular subaortic stenosis, perioperative parenteral antibiotics such as a β -lactam or a cephalosporin should be given 1 hour before surgery or dentistry and 6 hours after the procedure. Clindamycin may be useful as a prophylactic antibiotic for dental procedures. Prophylactic antibiotics for dogs with myxomatous valve degeneration undergoing a dental procedure is controversial since these dogs are not at an increased risk for development of IE; however, bacteremia does occur, and other tissues may be at risk.

Prognosis

Dogs with aortic IE have a grave prognosis, and median survival in one study was only 3 days compared to a median survival of 476 days for dogs with mitral IE (MacDonald et al., 2004). Dogs with *Bartonella* IE have short survival times since the aortic valve is almost exclusively affected. Similarly, in another case series 33% of dogs with aortic IE died within the first week, and 92% died within 5 months of diagnosis (Sisson, 1984). Glucocorticoid administration before treatment of IE is associated with higher mortality in dogs with IE (Calvert, 1982). Short-term death is most often caused by CHF or sudden death. Likewise, in humans with IE the presence of CHF has the greatest impact on poor prognosis. Other causes of death in dogs with IE within the first week of treatment include renal failure, pulmonary hemorrhage, and severe neurologic disease. Dilated Cardiomyopathy in Dogs

DANIEL F. HOGAN, *West Lafayette, Indiana*

HENRY W. GREEN, III, *West Lafayette, Indiana*

Dilated cardiomyopathy (DCM) is an idiopathic myocardial disease characterized by systolic and diastolic dysfunction with chamber dilation primarily involving the left ventricle and variable right ventricular changes. This disorder represents one of the most common acquired cardiac diseases in dogs (13.6%), with only degenerative valve disease (47.8%) and in some regions heartworm disease more prevalent. Typically DCM results in clinically important morbidity and mortality, including congestive heart failure (CHF) and sudden death, which is often secondary to ventricular arrhythmias. The latter appears to be breed related with the highest incidence within the Doberman pinscher and boxer breeds (Sisson, O'Grady, and Calvert, 1999) (see Chapters 175 and 176). This chapter considers the etiology, diagnosis, and chronic therapy of dogs with DCM. Chapter 171 provides additional recommendations for treatment of CHF, including hospital therapy.

ETIOLOGY

Systolic dysfunction with resultant cardiac dilation is thought to be the final common outcome of a variety of myocardial insults, including cytosolic, metabolic, immunologic, genetic, and infective mechanisms. In canine DCM most of these potential insults remain to be studied; thus the term *idiopathic* is most appropriate. Sporadically recognized causes of canine DCM include viral myocarditis, incessant tachycardia, taurine depletion, and possibly carnitine deficiency. In cases in which specific causes can be identified, an appropriate modifier should be used to describe the etiology of the disorder (i.e., taurine-deficiency cardiomyopathy). In humans familial inheritance of numerous genetic mutations, often those encoding cytoskeletal proteins, appear to be the most common basis for DCM and represent 20% to 50% of DCM patients (Wynne and Braunwald, 2001). The overrepresentation of certain breeds and familial inheritance patterns suggest a genetic cause for canine DCM as well. Recently the giant myofibrillar protein titin has gained considerable interest in Doberman pinchers (Meurs, 2005).

CLINICAL DIAGNOSIS

Although DCM generally is described as one disease, clinical signs and progression of the disease demonstrate some breed variation. Because of these differences, the specific breed should be considered when assessing an

individual animal with respect to etiology, therapeutic protocol, and prognosis.

Signalment and History

Dilated cardiomyopathy is usually considered a disease of large- and giant-breed dogs, with males generally having a higher incidence. Certain breeds are overrepresented, and there is some geographic variation. North American surveys suggest increased prevalence in the Doberman pinscher, Irish wolfhound, Great Dane, boxer and American cocker spaniel; whereas European surveys identified an increased risk for the Airedale terrier, Newfoundland, Doberman pinscher, and English cocker spaniel (O'Grady and Sullivan, 2004). Other breeds that we commonly observe include Dalmatians, German shepherds, and standard poodles. With the exception of the Portuguese water dog, in which clinical signs are often manifested before 12 weeks of age, DCM is commonly regarded as an adult-onset genetic disorder. Because of the potential benefit from early intervention, evaluation for occult (asymptomatic) disease can be considered in the breeds listed here. Clinical signs in dogs with DCM may be absent (preclinical or occult disease) or so subtle that they are overlooked. Some historical signs that should raise suspicion include mild exercise intolerance and weight loss. However, most often DCM is not diagnosed until clinical signs of overt CHF (coughing, tachypnea, dyspnea, and ascites) are present. As mentioned previously, sudden death is sometimes the first clinical sign of DCM in previously asymptomatic dogs.

Physical Examination

Although not present in every case, it is common for a soft (grade 1-3/6) systolic murmur to be heard over the mitral or tricuspid valve regions as a result of mitral or tricuspid valve insufficiency. Louder murmurs can be heard if there is concurrent degenerative valvular disease. A low-frequency early diastolic sound (S3 gallop) may be noted over the left apex, indicating ventricular dilation and elevated atrial pressure. Femoral arterial pulses are usually weak as a result of reduced stroke volume from decreased systolic function. Pulse deficits are the hallmark of an arrhythmia such as atrial fibrillation. Pulmonary auscultation may reveal crackles and increased bronchovesicular lung sounds secondary to pulmonary edema or muffled sounds if pleural effusion is present. Jugular venous distention, hepatomegaly, and ascites may be noted in dogs with biventricular CHF.

Electrocardiography

Most dogs with systematic DCM exhibit changes consistent with left ventricular enlargement and possibly left atrial enlargement. Cardiac arrhythmias, including sinus tachycardia, atrial fibrillation, and ventricular arrhythmias, are commonly identified. Conduction disturbances, including partial or complete left bundle branch blocks, are seen occasionally.

Ventricular premature complexes (VPCs) are common in Doberman pinschers and boxers with DCM and may require 24-hour ambulatory electrocardiographic (AECG) monitoring to fully characterize the rhythm disturbances. However, frequent VPCs may also be seen in boxers with what has been called *arrhythmogenic right ventricular cardiomyopathy* (previously described as boxer cardiomyopathy) (see Chapter 175) or similar clinical variant without concurrent DCM. The presence of VPCs may be a marker for occult DCM. Several studies in Doberman pinschers have found a clinical association between the number and complexity of ventricular arrhythmias and the development of DCM. One study demonstrated that nearly all dogs with frequent VPCs on AECG (>50 to 100/24 hour) went on to develop overt DCM (Sisson, O'Grady, and Calvert, 1999).

Atrial fibrillation appears to be more prominent in but not limited to giant-breed dogs such as Irish wolfhounds, Great Danes, and Newfoundlands. Two studies of giant-breed dogs revealed a 75% to 97% incidence of atrial fibrillation on initial presentation (O'Grady and Sullivan, 2004).

Thoracic Radiography

Dogs with DCM usually exhibit moderate-to-severe generalized cardiomegaly. Because of conformational differences (deep thorax and upright heart), Doberman pinschers and boxers often have less impressive radiographic changes. Pulmonary venous distention and pulmonary edema are the hallmarks of left-sided CHF, whereas pleural effusion is often a sign of biventricular CHF.

Echocardiography

Although a presumptive diagnosis of DCM can be made based on historical, physical examination, and ECG data, transthoracic echocardiography (TTE) allows a definitive diagnosis. Semiquantitative assessment of disease severity can also be determined. The hallmark of DCM from TTE is evidence of systolic dysfunction through alterations in multiple systolic indices, including reductions in percent fractional shortening, ejection fraction, and left ventricular area shortening along with increases in the E-point-to-septal separation and end-systolic diameter indexed to weight (Sisson, O'Grady, and Calvert, 1999). There is dilation of the left ventricle and left atrium (increased diameter indexed to weight). The thickness of the interventricular septum and left ventricular free wall are normal to decreased. The right ventricle and right atrium are variably affected and may appear normal to severely dilated. Mitral valve leaflet excursions typically are diminished because of low cardiac output and decreased venous return. Color Doppler often documents a central jet of mitral regurgitation derived from mitral annular and papillary muscle distortion, although

this may be prominent if there is concurrent degenerative mitral valve disease.

Diagnosis of affected dogs in the occult stage is far more difficult and controversial. In Doberman pinschers, in which occult disease has been studied most extensively, dilation of the left ventricle tends to precede systolic dysfunction; this may not be true for other breeds. Newer echocardiographic modalities may prove useful in the future to allow earlier detection of disease and potentially affirm equivocal results from TTE. One such modality is tissue Doppler imaging with determination of myocardial velocity gradient and mitral annular systolic motion velocity (S_m). Others include myocardial strain and left ventricular torsion. With further experience these novel techniques may be considered useful inclusions in any screening program for detection of occult DCM. Additional echocardiographic data that may differentiate equivocal cases include systolic time intervals, diastolic performance indices, and stress echocardiography.

PROGNOSIS

Generally DCM carries a guarded-to-poor prognosis, although this is influenced by factors such as etiology and stage of disease at the time of diagnosis. For example, DCM in some American cocker spaniels has been associated with taurine deficiency, in which supplementation (see section on Therapeutic Considerations) can result in improved function and prognosis. The prognosis for English cocker spaniels treated with conventional drugs only can be surprisingly long, often more than 2 years. Occult disease in Doberman pinschers can last from 2 to 4 years before overt disease develops, but it is not known if this holds true for other breeds. Once overt CHF is present, the prognosis is highly variable. In our experience most naive dogs (no treatment) with DCM that present in CHF and respond to initial therapy survive for at least 6 to 12 months, with some surviving 12 to 24 months and only a minority longer than 24 months. However, age at onset of CHF (younger is worse), breed, concurrent presence of dyspnea and ascites, and the presence of atrial fibrillation all appear to be negative prognostic indicators, as would be logical by the severity of the clinical signs (O'Grady and Sullivan, 2004).

THERAPEUTIC CONSIDERATIONS

There are many different views regarding the best therapeutic protocol for DCM and very few studies of high-grade evidence. It would seem reasonable, at least as a starting point, to parallel the commonly used triple-therapy protocol (diuretic, angiotensin-converting enzyme (ACE) inhibitor, and positive inotrope) from the human literature; and there are published data to support the use of furosemide, ACE inhibitors, and pimobendan in dogs.

Diuretics

Most dogs with DCM present in CHF; thus diuretics play a large role in initial treatment and long-term control of fluid retention. However, if CHF is absent at the time of

presentation, diuretics are not used because they result in further activation of detrimental neurohormonal responses. In addition, because of the unregulated activation of these responses, diuretics should never be used as sole therapy.

Furosemide

Furosemide is the most commonly used diuretic and has a rather large dosage range (2 to 4 mg/kg q24-8h orally [PO]). It is prudent to use the lowest possible dose to avoid adverse effects such as dehydration and hypokalemia. The concurrent use of ACE inhibitors and positive inotropes allows less dependence on diuretics. Therefore a lower required dosage of furosemide, often in the range of 0.5 to 2 mg/kg/day divided BID or TID, can be effective in some dogs. Another reason for using the lowest possible dose of furosemide is that, if excessive diuresis occurs while receiving ACE inhibitors, an acute reduction in glomerular filtration rate (GFR) can lead to acute renal failure.

Thiazides

With chronic refractory CHF the dosage of furosemide can be increased progressively, or another diuretic may be added. The thiazides (hydrochlorothiazide, 2.2 to 4.4 mg/kg q12h PO; chlorothiazide, 20 to 40 mg/kg q12h PO) are commonly chosen in this setting. The enhanced diuresis from their addition can be quite dramatic and, in fact, may be too great and result in dehydration, acute renal failure, and severe electrolyte derangements. We have found that the addition of these agents in a modified pulse therapy protocol (q12h given every third day) allows enhanced diuresis without inducing dehydration or hypokalemia. As the cardiac disease progresses, administration can be increased to every other day and then every day.

Spironolactone

Spironolactone, an aldosterone antagonist that has been classified as a potassium-sparing diuretic, can also be added to furosemide. Recent experimental data in dogs suggest that standard doses (2.2 to 4.4 mg/kg q12h PO) do not result in an appreciable diuresis in healthy dogs. The situation in CHF is less certain. Historically spironolactone has been used to help prevent hypokalemia induced by chronic diuretic therapy in the pre-ACE inhibitor era. With the advent of ACE inhibitor therapy, there was concern that concurrent use of spironolactone with ACE inhibitors might result in hyperkalemia from excessive

depression of aldosterone action and levels, respectively. However, clinically this is not commonly recognized and might be the result of the well-recognized phenomenon of aldosterone escape with ACE inhibitor therapy. Routine monitoring of potassium levels in dogs receiving concurrent spironolactone and ACE inhibitors is prudent, and excessive potassium intake should be avoided.

Angiotensin-Converting Enzyme Inhibitors

The development of ACE inhibitors has made perhaps the greatest impact on medical management of DCM over the past 50 years. These agents prevent the formation of angiotensin II, which induces vasoconstriction, fluid retention, myocardial and vascular smooth muscle hypertrophy/fibrosis, aldosterone release, and enhancement of sympathetic nervous system activity. There are numerous drugs within the ACE inhibitor class; and, although there are some unique differences among the individual drugs, beneficial effects are seen across the class when used in dogs with DCM. These benefits include reduced signs of CHF and improved survival. Enalapril and benazepril are probably the best studied in dogs, but this is changing rapidly as additional drugs within this class become approved for use in dogs in Europe (Table 174-1).

Unlike in mitral insufficiency, there appears to be a therapeutic role for ACE inhibitors in dogs with DCM of all stages because the renin-angiotensin-aldosterone system is activated early in the course of DCM, even before development of CHF. Many of these agents are labeled for use once or twice a day, but we generally use enalapril at a dosage of 0.5 mg/kg every 12 hours orally, especially with CHF. Some clinicians initiate therapy at 0.25 mg/kg every 12 hours orally and increase the dosage after follow-up renal function tests. Potential adverse effects for drugs of this class include gastrointestinal (inappetence, vomiting), renal (acute renal insufficiency), and hypotension. However, in our experience it is very uncommon for dogs to experience clinically evident hypotension. This may be because of a species difference in sensitivity to these drugs. The greatest risk appears to be a reduction in GFR usually associated with volume depletion, possibly from aggressive diuretic use. Therefore routine monitoring of renal parameters is recommended in dogs receiving ACE inhibitors. This is commonly done in practice by measuring renal values before drug therapy, 3 to 5 days after starting therapy or increasing dose or dosing frequency

Table 174-1

List of Commonly Used Angiotensin-Converting Enzyme Inhibitors in Dogs and Cats

Generic Name	Trade Name	Dose (Dog)	Dose (Cat)
Benazepril	Fortekor, Lotensin	0.25-0.5 mg/kg q24-12h	0.25-0.5 mg/kg q24-12h
Enalapril	Enacard, Vasotec	0.25-0.5 mg/kg q24-12h	0.25-0.5 mg/kg q24-12h
Imidapril	Prilium	0.25 mg/kg q24h	
Lisinopril	Prinivil, Zestril	0.25-0.5 mg/kg q24-12h	0.25-0.5 mg/kg q24h
Ramipril	Altace	0.5 mg/kg q24-12h	0.5 mg/kg q24h

of the ACE inhibitor or diuretic, and every 3 to 6 months while on chronic stable therapy. Renal values should also be measured any time a dog exhibits clinical signs such as vomiting, inappetence, or reduced urination. The concurrent use of nonsteroidal antiinflammatory drugs may increase the risk of renal insufficiency and reduce the clinical efficacy of these drugs. Two drugs within this class that should be highlighted because of their unique pharmacokinetic properties are lisinopril and benazepril. Lisinopril, unlike the remainder of the ACE inhibitors, is not a prodrug. Therefore it does not require metabolism to the active metabolite and can be used in dogs with concurrent hepatic insufficiency. Benazepril is excreted through both renal and hepatic routes and therefore does not appear to require altered dosing in dogs with mild-to-moderate concurrent renal insufficiency. The therapeutic advantage of these characteristics requires further study.

Positive Inotropes

Increasing the strength of ventricular contractions in dogs with ventricular systolic dysfunction is naturally intuitive. However, only a few oral drugs confer a positive inotropic effect. These drugs as a class are associated with increased frequency of ventricular arrhythmias, especially in humans. The arrhythmogenic potential of inotropic drugs in dogs requires more study.

Digitalis Glycosides

Until recently digoxin was the only positive inotrope available orally in many countries, including the United States. Digoxin not only exhibits a weak inotropic effect but has the additional benefit of neurohormonal modulation. This results from a normalization of baroreceptor function, which leads to reduction in sympathetic and enhancement of parasympathetic nervous system activity. Although there has been no prospective study in veterinary medicine to evaluate the clinical efficacy of digoxin in DCM, there are anecdotal reports of increased quality of life. A large clinical trial in humans demonstrated reduced cardiovascular mortality, an overall significant reduction in hospital visits, and an improvement of quality of life. In addition, lower blood levels of digoxin have been shown to confer measurable benefits while reducing the risk for toxicity. There is a trend among veterinary cardiologists to achieve digoxin levels that are lower than those previously accepted as therapeutic in dogs (approximately 1 to 2 ng/ml). We prefer to use a dosing protocol of 0.003 to 0.005 mg/kg every 12 hours orally; the lower end is used for medium and large dogs or in dogs with concurrent renal insufficiency since digoxin is cleared primarily by the kidney. In very large dogs we often use 0.22 mg/m² every 12 hours orally, but the initial dose should never exceed 0.25 mg every 12 hours. Digoxin levels are required to monitor therapy so appropriate up-or-down dose titrations can be made. In our practice digoxin levels are usually measured 6 to 8 hours after dosing, 7 to 10 days after initiating or changing the dose, whenever renal insufficiency is recognized or clinical signs of toxicity are present (inappetence, vomiting, diarrhea, arrhythmias), or every 6 months with stable chronic therapy. Some cardi-

ologists prefer to sample a trough 10 to 12 hours after the previous dose; however, this timing can be more difficult to achieve in the outpatient clinic. If toxicity is suspected, therapy should be discontinued until the digoxin level is known. For uncomplicated cases we consider levels from 0.7 to 1.5 ng/ml to be therapeutic. If toxicity is suspected within this range, we consider cutting the dose in half to see if signs abate. If clinical signs persist, we consider concurrent medication, or clinical disease. Higher serum levels (1.5 to 2.5 ng/ml) may be required to help manage atrial fibrillation with attendant risk of adverse effects. When atrial fibrillation with rapid ventricular response rate (>200 beats/min) is present, an oral loading protocol of 0.003 to 0.005 mg/kg every 8 hours orally for 48 hours can be used. This hastens the development of a therapeutic level.

Pimobendan

Pimobendan (Vetmedin) is a positive inotropic drug recently approved for use in dogs. The positive inotropic effect is caused by an increased sensitivity of troponin C for calcium and also by phosphodiesterase III inhibition. The latter mechanism also results in venous and arterial vasodilation, which is the reason this drug is referred to as an "inodilator." Pimobendan also exhibits beneficial neurohormonal effects, which include a reduction in plasma norepinephrine levels and inflammatory cytokines such as tumor necrosis factor (TNF)- α and interleukin (IL)-1 β . Adverse effects could include an increase in sinus rate and enhanced arteriovenous nodal conduction. Whether or not pimobendan is proarrhythmic requires more study. Clinical studies in dogs have revealed improved survival and improved quality of life and functional class of heart failure (Luis Fuentes, 2004). The standard dosing protocol is 0.25 to 0.3 mg/kg every 12 hours orally.

Antiarrhythmic Therapy

Supraventricular Arrhythmias

Cardiac arrhythmias are commonly encountered with DCM, with atrial fibrillation most frequently requiring clinical management. The focus of atrial fibrillation treatment is management of the ventricular response rate in most cases. However, pharmacologic and electrocardioversion techniques have been used successfully in some dogs (see Chapter 164). Pharmacologic management of atrial fibrillation is centered on slowing atrioventricular (AV) nodal conduction velocity through the use of digoxin, calcium channel blockers, and β -blockers. Digoxin is usually the first-line drug but is often ineffective by itself. For this reason diltiazem (0.5 to 1.5 mg/kg q8h PO) or atenolol (0.5 to 1 mg/kg q24–12h PO) is commonly added to the protocol. The β -blockers are hampered by the risk of decompensation at the doses commonly required to effectively control the ventricular response rate. For this reason we most commonly add diltiazem to digoxin and find this combination very effective. The use of cardio-protective β -blocker therapy for CHF will be discussed separately.

Ventricular Arrhythmias

Certain breeds have a higher incidence of ventricular arrhythmias, including boxers and Doberman pinschers (see Chapters 175 and 176). The class III agents (sotalol, amiodarone) appear particularly effective at abolishing these arrhythmias. However, sotalol (1 to 2 mg/kg q12h PO) does have β -blocking properties and should be used very cautiously in these patients to avoid cardiac decompensation, although this is not a complete contraindication. Amiodarone (10 mg/kg q24–12h PO for 7 to 10 days and then 5 to 10 mg/kg q24h PO) can be a very effective antiarrhythmic drug with less negative inotropy than sotalol. However, amiodarone can be associated with adverse effects, including hepatotoxicity and altered thyroid function. The class Ib drug, mexiletine (4 to 10 mg/kg q8h orally) also appears to be quite effective. Efficacy may be enhanced with concurrent use of atenolol, sotalol, or another β -blocker.

Ancillary Treatments

Nutritional Therapy

Amino acid supplementation. There is growing evidence that amino acid deficiencies may be more common in dogs with DCM than previously suspected, but these cases still comprise a small minority of the DCM population (Bonagura, 2000). The prevalence of carnitine deficiency with DCM does not appear large, and many dogs do not demonstrate a clinical response to supplementation alone. An accurate diagnosis usually requires an endomyocardial biopsy because serum levels are often normal or even elevated with myocardial deficiency. Carnitine supplementation (50 to 100 mg/kg q12–8h PO) is relatively expensive but may be helpful in some dogs. Taurine deficiency has also been recognized, especially in some specific breeds such as the American cocker spaniel, golden retrievers, and Newfoundlands and in dogs eating custom and lamb-rice diets. Unlike carnitine, an accurate assessment of taurine status can be determined by measuring serum or whole blood levels, and supplementation has been associated with a positive clinical response. Taurine levels should be measured when DCM is recognized in a dog from one of the previously mentioned breeds, in a breed uncommonly diagnosed with DCM, or in a dog receiving an unusual or unbalanced diet. Taurine supplementation (500 mg q12h PO) should be given to dogs with a documented deficiency or while levels are pending in dogs suspected as being deficient. Taurine supplementation is not expensive; thus a 3- to 6-month therapeutic trial in lieu of a documented deficiency could be considered.

Reduced sodium intake. Reduced dietary intake of sodium helps prevent excessive fluid retention and less dependence on diuretics. Modest-to-moderate sodium restriction is prudent, but excessive restriction results in reduced diet palatability and possibly activation of neurohormonal systems. We have found the following diets helpful: Purina (CV, NF) and Hill's (k/d, g/d, and h/d). However, this list should not be considered exhaustive. See Chapter 157 for more details about diet and supplementation.

Antioxidants

There is some evidence that antioxidants may play a beneficial role in cardiovascular disease through reduction in

inflammatory cytokines (i.e., TNF- α and IL-1 β). Supplementation with omega-3 fatty acid products (780 mg of eicosapentaenoic acid [EPA] and 497 mg of docosahexaenoic acid [DAA] per day) is safe, inexpensive, and has been shown to exhibit beneficial effects (Smith, 2007).

β -Blockers. Chronic activation of the sympathetic nervous system can result in myocardial remodeling, fibrosis, and reduced function. Clinical data from humans suggest that chronic β -blocker therapy results in improved cardiac function and survival. Although data are absent in veterinary medicine, it is possible that dogs with DCM may also benefit from these agents. However, these agents can cause decompensation if the dose is too high or the animal particularly sensitive to sympathetic withdrawal. For these reasons these drugs should only be used in dogs with occult or compensated disease, or treated DCM and at very low initiating doses. The two drugs that have received the most attention in veterinary medicine are metoprolol and carvedilol. Both of these drugs provide nonspecific β -blockade; but carvedilol also exhibits potent antioxidant properties and α -blockade, although this last effect seems to be weak and may not exert a clinical impact. Both of these agents appear to be relatively safe in dogs when used in a slow up-titration dosing regimen (metoprolol, 0.1 mg/kg q12–8h PO; carvedilol, 0.04 to 0.1 mg/kg q12h PO) when the dose is increased every 7 to 14 days to a maximum tolerated dose or 1 mg/kg for either drug (Abbott, 2004).

Spironolactone. Spironolactone may exhibit a weak diuretic effect at best in the dog, but it may hold greater promise as an antimitogenic agent by interfering with the remodeling and fibrotic effects of aldosterone. In a large human clinical trial it was found that the addition of a once-a-day, subdiuretic dose of spironolactone to standard cardiac therapy resulted in a reduction in overall mortality by more than 30%. Although there are no clinical data in veterinary medicine to support a similar effect in dogs with DCM, it is now common to use spironolactone in this manner. There is no established once-a-day low dose for dogs, but we use an empiric regimen of 6.25 mg q24h orally for dogs less than 10 kg, 12.5 mg q24h orally for dogs 10 to 25 kg, and 25 mg q24h orally for dogs more than 25 kg.

Intermittent dobutamine infusion. Dobutamine is a very effective drug for treatment of cardiogenic shock in dogs with DCM (see Chapter 171). It has been documented in the human literature that some chronic refractory heart failure patients demonstrate a positive clinical response to intermittent dobutamine therapy. These beneficial effects are sometimes seen for a period of time longer than the infusion period. We have used this protocol occasionally; dobutamine is infused at 5 to 10 mcg/kg/min intravenously for a 12- to 24-hour period. It is difficult to say whether this therapy is effective, but some dogs seem to have had a positive clinical response.

CHAPTER 175

Cardiomyopathy in Boxer Dogs

KATHRYN M. MEURS, *Pullman, Washington*
ALAN W. SPIER, *Tampa, Florida*

Boxer cardiomyopathy is a primary myocardial disease that typically presents in one of three forms: an asymptomatic form with ventricular premature complexes (VPCs); a symptomatic form with VPCs; and a form with ventricular dilation, myocardial dysfunction, and ventricular and supraventricular tachyarrhythmias. Affected dogs may live for years with the disease and remain asymptomatic, may die of sudden death, or may gradually progress to congestive heart failure. This disease is most commonly referred to as *arrhythmogenic right ventricular cardiomyopathy (ARVC)*. ARVC is an adult-onset familial disease that appears to be inherited in an autosomal-dominant fashion. The frequency of disease, as well as disease severity, increases with age.

A small percentage of boxers with myocardial disease present for the first time with ventricular dilation and myocardial dysfunction without a history of ARVC. It is possible that these boxers have a separate myocardial disease with an etiology that might include an inherited carnitine deficiency, viral myocarditis, or some other myocardial insult that results in the development of a cardiomyopathic state.

DIAGNOSIS

Arrhythmogenic Right Ventricular Cardiomyopathy

A single diagnostic test for boxer ARVC is unavailable, and the diagnosis is best based on the presence of a combination of findings that may include a family history of disease, the

presence of a ventricular tachyarrhythmia, a history of syncope or exercise intolerance, and the exclusion of other systemic and cardiovascular diseases that could be responsible for the clinical presentation. Generally a thorough physical examination, electrocardiogram, blood pressure measurement, and echocardiogram should be performed when a diagnosis is suspected. In addition, a Holter monitor provides important information for both the initial treatment and long-term management of the case and should be performed whenever possible.

Physical examination findings may include the auscultation of a tachyarrhythmia, although it should be emphasized that many affected dogs have very intermittent bouts of the arrhythmia and the absence of a tachyarrhythmia during examination does not rule out the diagnosis. In addition, since this is primarily an electrical disease, the majority of affected boxers do not have a heart murmur, although a left apical systolic murmur of mitral regurgitation may be identified in the cases that also have myocardial dysfunction and many boxers have a left basilar ejection murmur of uncertain etiology.

The classic electrocardiographic findings of ARVC include the presence of an upright VPC (left bundle branch block morphology) on a lead II electrocardiogram (Harpster, 1991). However, some affected dogs have a different morphology to their VPCs; or, since the arrhythmia is so intermittent, the electrocardiogram may not demonstrate any VPCs at all. It is important to note that a normal electrocardiogram does not exclude a diagnosis of ARVC; if suspicion exists because of clinical signs (syncope, exercise

intolerance), auscultation of an arrhythmia, or a family history of disease, a 24-hour Holter monitor is strongly suggested. Even if occasional VPCs are identified on an in-house electrocardiogram, we generally recommend a Holter monitor to help provide the best assessment of overall frequency and complexity of the arrhythmia. In addition, a pretreatment Holter provides useful information when attempting to determine the efficacy and the potential proarrhythmia of treatment once it has started.

The results of the Holter monitor can be very useful in establishing a diagnosis of ARVC, particularly if the electrocardiogram is within normal limits. It is unusual for mature adult dogs to have ventricular ectopy. The median number of VPCs detected on the Holter reading from 600 mature asymptomatic boxers was 10 VPCs in 24 hours. Therefore the identification of frequent ventricular ectopy (>100 VPCs/24 hours) in an adult boxer is strongly suggestive of a diagnosis of ARVC, particularly if there is significant complexity (couplets, triplets, bigeminy, or ventricular tachycardia) to the arrhythmia. However, in some cases a diagnosis of ARVC in the boxer is greatly suspected based on the breed and presence of syncope, but the Holter monitor reading is not clearly abnormal. This may be because of the significant day-to-day variability of VPC number (up to 83%) in affected dogs. In highly suspect cases it may be worth performing a second Holter monitor or an event monitor if the dog is syncopal.

A blood pressure measurement and echocardiogram are recommended in cases of suspect ARVC. Although in the majority of cases the blood pressure, cardiac chamber sizes, and systolic function are within normal limits, an echocardiogram can rule out other less common causes of ventricular ectopy (e.g., neoplasia). Blood pressure measurement may give insights into additional systemic diseases that are capable of causing syncope. In addition, the echocardiogram is necessary to identify the small percentage of dogs with ARVC that develop right and left ventricular enlargement and myocardial dysfunction.

Dilated Cardiomyopathy

A small percentage of boxers have a clinical presentation consistent with dilated cardiomyopathy. Affected dogs may present with syncope or signs of left heart failure, including coughing; tachypnea; or biventricular failure, including coughing, tachypnea, and ascites. Thoracic radiographs may demonstrate left or biventricular enlargement, pulmonary edema, and pulmonary venous congestion. The echocardiogram may demonstrate left or biventricular enlargement with systolic dysfunction. The etiology of these cases is unknown. A small percentage of the cases may have progressed gradually from ARVC; however, other etiologies for myocardial dysfunction, including L-carnitine deficiency or myocarditis, should be considered.

SCREENING

Given the inheritable nature of ARVC, there is significant interest by breeders and enthusiasts of the boxer breed

for the development of a screening program. However, at this time there is no single ideal screening test, and consideration should be given to multiple factors, including a family history of ARVC and repeated abnormal Holter monitor readings. Given the adult-onset nature, many perform the first Holter monitor at the age of 3 years and continue on an annual basis. Holter monitor results should be evaluated for both the number of VPCs and the complexity of arrhythmia (e.g., singles, couplets, triplets, ventricular tachycardia). However, there are still many unanswered questions about ARVC and the relationship of the ventricular arrhythmia to the development of clinical signs. Some affected dogs can have thousands of VPCs and never develop clinical signs; others demonstrate severe clinical signs with a fairly low number of VPCs. We have not found the number of VPCs or the complexity of the arrhythmia to be statistically different in symptomatic (syncopal) dogs compared to asymptomatic affected dogs. Therefore the factors that determine which dogs will eventually become clinical for the disease are not known, which leads to additional frustration in screening for this disease. Breeders should be strongly encouraged to screen for the disease but should be advised about the significant complexities of screening and counseled not to remove dogs completely from a breeding program because of a single abnormal Holter reading. Annual Holter monitoring is strongly recommended, and an emphasis should be placed on the results of multiple annual Holters in an asymptomatic animal.

The results of 24-hour Holter monitoring from over 600 asymptomatic adult boxers identified a median number of VPCs of 10, with 25% and 75% confidence intervals of 2 and 110 VPCs per 24 hours, respectively. Based on this information we have developed the following initial system for screening asymptomatic dogs.

1. 0 to 50 single VPCs/24 hour: interpreted as within normal limits
2. 51 to 100 VPCs/24 hours: interpreted as indeterminate; suggest repeating in 6 to 12 months
3. 100 to 300 single VPCs/24 hours: interpreted as suspicious; consider keeping out of the breeding program for 1 year and repeating the Holter study
4. 100 to 300 VPCs/24 hours with increased complexity (frequent couplets, triplets, ventricular tachycardia) or 300 to 1000 single VPCs/24 hours: interpreted as likely affected
5. More than 1000 VPCs/24 hours: interpreted as affected, may consider treatment as discussed in the following paragraphs

These criteria are based on the evaluation of single Holter monitors in mature boxers with no history of syncope. Additional studies to evaluate the long-term outcome of boxers with arrhythmias are currently being performed. This information has been provided as a possible starting point for making screening recommendations. Multiple criteria should be considered for each dog before making any strict recommendations, including family history, evidence of any ongoing systemic disease that could be associated with the development of the ventricular arrhythmia, and repeated Holter studies.

TREATMENT

In affected boxers antiarrhythmic therapy has been shown to decrease the number of VPCs, the complexity (grade) of the arrhythmia, and the presence of syncope (Meurs et al., 2002). However, the ability of antiarrhythmic therapy to decrease the risk of sudden death in affected dogs has never been proved or disproved. In addition, ventricular antiarrhythmics can demonstrate important proarrhythmic effects. Therefore the risks and benefits should always be assessed when considering treatment. In the asymptomatic dog we generally recommend therapy to decrease the number and complexity of the arrhythmias if there are at least 1000 VPCs/24 hours or if runs of ventricular tachycardia or evidence of the R-on-T phenomenon exist. It should be remembered that some ARVC dogs die of sudden death without ever having any documented episodes of syncope; thus the absence of a syncopal history does not imply a lack of risk. Ideally boxers with syncope and ventricular arrhythmias should be treated after a 24-hour Holter monitor is performed to quantify the pretreatment arrhythmia. If the syncope is frequent or ventricular tachycardia is observed, a Holter monitor evaluation may not be performed so that therapy can be started as soon as possible. However, in these cases the absence of a pretreatment monitor may make it difficult to fully assess the response to therapy. Therefore, whenever possible, a Holter monitor evaluation is performed first, and the owner is then advised to start therapy immediately after removing the Holter (before the results are available) if great concern exists.

Two therapeutic protocols appear to be most effective at reducing the number of VPCs and the degree of complexity of the arrhythmia. The first is sotalol (1.5 to 2.5 mg/kg q12h orally [PO]); the second is a combination of mexiletine (5 to 6 mg/kg q8h PO) with a β -blocker (atenolol (0.5 mg/kg q12h PO) or sotalol (1.5 to 2 mg/kg q12h PO)). Sotalol as a monotherapy is generally chosen first because of the low level of side effects and ease of dosing twice a day. However, in some dogs sotalol is less effective. In these cases adding mexiletine or switching to mexiletine and atenolol may be useful. Mexiletine can cause a loss of appetite or mild gastrointestinal upset, but the addition of a β -blocker allows a lower dose of mexiletine to be used to help reduce this side effect. In addition, mexiletine should always be given with a meal.

Despite their potential for beneficial antiarrhythmic effects, the medications listed here can have a proarrhythmic

effect or may be less effective in some individual boxers with ARVC. Therefore, if possible, patients should be managed by assessing both a pretreatment and posttreatment (2 to 3 weeks after starting treatment) Holter monitor evaluation. This can help determine the effect of treatment and confirm that the arrhythmia has not gotten worse. Significant day-to-day variability (up to an 83% change in daily VPC number) has been observed in affected boxers (Spier and Meurs, 2004). Therefore a therapeutic response is considered when at least an 80% reduction in VPC number and a reduction in the complexity of the arrhythmia are observed on the posttreatment Holter reading. In addition, an increase in symptoms after starting treatment or a greater than 80% increase in the number of daily VPCs may suggest a proarrhythmic effect.

New Advances in Therapy

The use of implantable cardioverters-fibrillators has gained popularity in humans with ventricular tachyarrhythmias. A defibrillator was successfully placed in one boxer with ARVC, although some complications were observed that were associated with programming limitations of the device. The long-term benefits of this type of therapy in dogs with this myocardial disease have yet to be studied.

Cardiomyopathy in Doberman Pinschers

CLAY A. CALVERT, *Athens, Georgia*

KATHRYN M. MEURS, *Pullman, Washington*

Cardiomyopathy (CM) in Doberman pinschers (DPs) is a common, inherited, slowly progressive primary myocardial disease. Based on anecdotal reports, we believe that CM in this breed was present in the United States and Canada as far back as the mid-1940s and the incidence of CM in DPs has reflected the breed population since that time. The hallmarks of CM in DPs are heart rhythm disturbances (mostly ventricular tachyarrhythmia, sudden death [SD], or end-stage congestive heart failure [CHF]).

Affected DPs appear to progress through a long asymptomatic preclinical or occult phase (Fig. 176-1). Ventricular premature complexes (VPCs) are often the first markers for CM in this stage and are initially infrequent. Some DPs have slightly increased left ventricular internal dimensions for several years, even from early adulthood, before VPCs appear. Holter recording evaluation is usually needed for earliest detection of VPCs, and the echocardiogram parameters are usually within the “normal” ranges at that time. Typically within 1 year after ventricular ectopy is identified the echocardiogram findings become equivocally abnormal. Within 2 years the echocardiogram findings become unequivocally abnormal. As left ventricular dilation and contractility worsen, VPCs tend to worsen, and potentially lethal ventricular tachycardia (VT) develops in at least 50% of affected DPs. SD is often the first sign of CM and is the outcome in 30% to 50% of patients. It typically occurs between 6 and 8 years of age, is associated with at least moderate dilation and decreased contractility of the left ventricle, and often occurs about 1 year before overt CHF would be anticipated. Over 50% of all overtly healthy DPs over 10 years of age have numerous VPC and/or echocardiographic abnormalities. Many of these DPs die of comorbid disease, and CM is often not identified because cardiac workups have not been performed.

ETIOLOGY AND GENETICS

The breeding history of the DP in North America is one of extreme inbreeding. Until recently virtually all DPs born in the United States and Canada could be traced to one of seven sires. “The seven sires” came from champion German stock imported into the northeastern United States and Canada during the late 1930s and early 1940s and were all closely related; the older three sired the younger four. Three of the seven died suddenly and unexpectedly in middle age. Many related DPs have been

exported throughout Europe since 1945, and many have been exported throughout the world in the past 30 years. In many cases the sires and/or dams of these dogs have subsequently died of CM. There is a distinct American flavor to the Dutch, English, and Australian DP. In addition, we have identified CM in numerous DPs imported to the United States from Europe. However, in general we believe that the incidence of CM in Europe is lower than in the United States and Canada.

Although CM is known to be a familial disease, the genetics in DPs are not well understood. In humans approximately 25% to 30% of all cases are familial and can be autosomal dominant (about 50%), autosomal recessive, or X-linked. The mode of inheritance in DP was suggested to be autosomal dominant in one retrospective study. Mutations, usually single, each causing CM in humans, have been identified in most of the proteins of the sarcomere, cytoskeleton, and sarcolemma. If CM in DPs is an autosomal-dominant trait, it should appear with almost equal prevalence in both genders, and there should not be any silent carriers. All affected dogs should have at least one affected parent. However, in some cases it may appear as if neither parent was affected if the dogs died of noncardiac disease before the CM has developed. Although several studies have been performed to try to determine the molecular basis for the disease, and two genes (actin, desmin) have been eluded, the genetic etiology remains undefined.

SCREENING AND EARLY DIAGNOSIS

We strongly recommend annual screening of adult DPs for preclinical CM. Without careful screening SD is often the first sign of CM, or CM is unrecognized until the end-stage of CHF is reached. CHF carries a short and subsequent survival time of less than 1 to 6 months (mean 3 to 4 months) in most DPs treated with conventional drugs. Screening should include both echocardiography and Holter monitor evaluation beginning at 2 to 3 years of age. The likelihood of finding VPCs and echocardiographic markers for CM increases with age.

The most important Holter recording markers for CM are VPCs that usually arise from the left ventricle. Twenty-four-hour Holter recordings containing more than 50 VPCs, any couplets or triplets of VPCs, or runs of VT indicate in our experience that the echocardiogram will be abnormal or equivocally progress to this stage within 1 year. Statistical analyses of large numbers of DPs

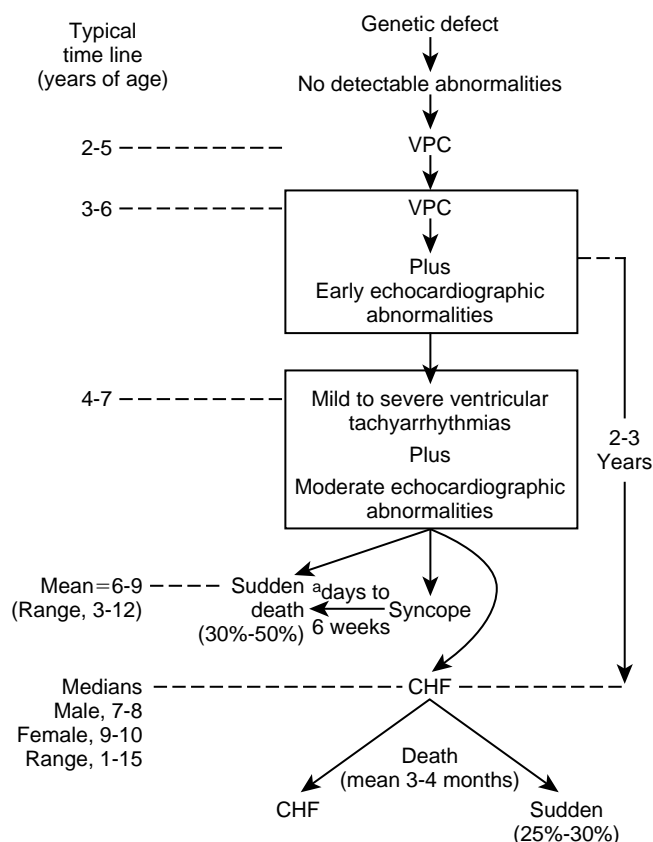

Fig. 176-1 Typical evolution of cardiomyopathy in Doberman pinschers. Arrhythmia and echocardiographic abnormalities can begin as early as 1 year of age or as late as at least 11 years of age. Disease evolution is accelerated when markers appear at a young age and is slower when markers first appear at old age. Syncop^a due to ventricular tachycardia is a marker that survival to the end-stage of congestive heart failure is unlikely; rather sudden death intervenes in spite of therapy.

indicate that even one VPC correlates with increased risk of CM. However, for any one DP, on rare occasions fewer than 50 isolated VPCs may be considered "normal." Any VPC detected during static electrocardiogram (ECG) in DPs is probably the result of CM unless another etiology can be identified. Arrhythmias can begin as young as 9 to 12 months of age and often begin around 2 to 4 years of age; by 6 years of age about 50% of all overtly healthy DPs have VPCs. In DPs with normal to equivocally abnormal echocardiograms the severity of arrhythmia is generally mild, total VPCs/24 hours vary from less than 100 to a few thousand, and life-threatening VT is generally absent. Rapid VT is common after the left ventricular end-systolic dimension exceeds 40 mm, end-systolic dimension exceeds 50 mm, and the fractional shortening declines to less than 23%. Although arrhythmias very often begin when echocardiographic parameters are within the normal ranges, retrospective analyses of serial echocardiograms in these DPs indicate that these parameters progressively change from normal to abnormal. By 1 to 2 years after the onset of VPCs, echo parameters become unequivocally abnormal. Thus, unless screening is begun at 2 to 3 years of age, the odds are that, when the arrhythmias are first

detected, even by Holter recordings, the echocardiogram will be abnormal.

The standard ECG is useful if VPCs are detected, and in most cases at least moderate dilation and systolic dysfunction of the left ventricle are present. Prolongation of the P wave and/or QRS complex duration often correlates with severe myocardial failure. Without treatment, SD or CHF is likely within 9 months. Low-voltage, wide R waves with a "sloppy" or slurred down-stroke of the R wave also suggest advanced myocardial failure and impending CHF.

Compared to age, gender, and size, matched breeds of dogs that have a low incidence of CM, it is our experience that the heart of most normal DPs is not as muscular. Thus the normal echocardiographic parameters that we use are specific for the DP. The most useful M-mode echocardiographic markers of occult CM in order of importance are left ventricular end-systolic dimension, end-diastolic dimension, and fractional shortening. The distinction between a normal and equivocally abnormal echocardiogram is confounded by the limited accuracy of the test, interexaminer variability, and stress level (adrenaline) during the test. Generally overt signs of depressed left ventricular function in sedentary dogs are not evident until the left ventricular end-diastolic dimension and fractional shortening are greater than 55 mm and less than 20%, respectively. In active dogs the owners may recognize exercise intolerance in dogs with mild ventricular dysfunction but often attribute it to age.

Mitral regurgitation (MR) is found by Doppler when the left ventricular end-systolic dimension is moderately increased. MR is often the result of dilation and decreased systolic contraction of the annulus or papillary muscles, but myxomatous mitral and tricuspid valve degeneration are also common in middle-aged and older DPs. MR is relatively severe in some DPs and confounds the differential diagnosis of "large-dog MR" versus CM. Moderate-to-severe MR facilitates fractional shortening and worsens left atrial dilation. In these DPs left atrial dilation is disproportionately severe relative to reduced fractional shortening compared to DPs with mild CM and mild MR. However, standard ECG and Holter recordings from these DPs consistently demonstrate ventricular ectopy, and SD is sometimes the outcome.

SYNCOPE

Syncop^e in DP is usually caused by rapid, sustained VT. The likelihood of surviving an episode of rapid, sustained VT is probably related to the left ventricular ejection fraction. The lower the ejection fraction, the more likely VT will degenerate to fibrillation and cause SD. Aggressive antiarrhythmic treatment is indicated and usually retards SD, but our experience is that "syncopal" dogs nonetheless will die suddenly usually within 1 year. A less common cause of collapse in this breed is reflex-mediated (neurocardiogenic) syncop^e. This is an adrenergic-stimulated vagal reflex of bradycardia and vasodilation triggered by fight, flight, fright, or startle scenarios. In this breed neurocardiogenic bradycardia can be benign but is still a marker for CM and must be distinguished from VT-induced episodic weakness or syncop^e. The presence

of numerous VPCs or VT contained in routine ECG or Holter recording indicates VT as the likely cause of syncope. The onset of atrial fibrillation can also precipitate episodic weakness and syncope.

SUDDEN DEATH

Sudden death is the outcome in at least 30% of affected DPs, is as high as 50% in some lines, and exceeds 50% in some families. Syncope, presyncope, and SD are the result of sustained (greater than 30 seconds), rapid VT. If VT stops spontaneously, the patient quickly recovers; but SD is the outcome if the VT degenerates into ventricular fibrillation. Premonitory events of syncope may not precede SD; in other words, the first faint is the last one. Should spontaneous recovery occur and antiarrhythmic treatment not be initiated, another episode is likely within hours to weeks. Rarely does a DP survive three separate episodes. Left untreated, syncope or presyncope caused by VT usually is followed by SD within 1 or 2 weeks, and survival beyond 6 weeks is rare. Sudden death occurs more often in the morning and during or immediately following exertion-excitement, but it can occur during sleep.

In our experience life-threatening ectopy does not occur until left ventricular systolic function is at least moderately depressed. Lethal VT is often associated with end-diastolic dimension greater than 50mm, end-systolic dimension greater than 45mm, and fractional shortening between 18% and 23%. Among the surviving subset, progression of left ventricular dysfunction is associated with a lower incidence of SD until the onset of CHF.

TREATMENT GUIDELINES

There is no general agreement regarding treatment guidelines for occult CM. We recommend treatment for myocardial failure when the echocardiogram is unequivocally abnormal (i.e., when the left ventricular end-systolic dimension is greater than 40mm, the end-diastolic dimension is greater than 50mm, and the fractional shortening is less than 25%). Ideally treatment is based on all three parameters, but in selected DP it may be based on one or two measures because early myocardial failure is not always "textbook". In addition, we usually do not initiate treatment until the E-point-to-septal separation is greater than 10mm, a finding typical of ventricular dilation and myocardial failure.

Based on studies in humans, three available classes of drugs may exert a favorable influence on progression of myocardial degeneration and systolic dysfunction: angiotensin-converting enzyme (ACE) inhibitors, aldosterone receptor antagonists, and β -adrenergic receptor blockers. There is little documentation on the influence of these drugs on disease progression in DPs with occult CM. We believe that therapy with an ACE inhibitor initiated before onset of CHF can significantly retard the progression of myocardial failure or CHF. Suggested dosage schedules include enalapril (Enacard, Meril; 0.25mg/kg q12h orally [PO] for 1 week and then 0.5mg/kg q12h orally) or benazepril (Lotensin, Novartis; 0.25mg/kg q24h PO or q12h for 1 week and then 0.5mg/kg q 24h PO or q12h PO). Also consider spironolactone (Aldactone, Searle; 1 to 2mg/kg q 12h PO) in combination with the

ACE inhibitor at this stage. Spironolactone exerts potentially beneficial actions on the myocardium and vasculature. The ACE inhibitor-spironolactone combination increases potassium and magnesium serum concentrations, which may reduce arrhythmia. Spironolactone may exert an antifibrotic action (blocking cardiac fibroblast receptors) and may slow progressive myocardial fibrosis. β -Blockade has been shown in numerous human studies to exert a favorable influence on both SD risk and progression of myocardial degeneration. Clinical studies in DPs have not been reported. The addition of carvedilol to the treatment regimen 2 weeks after initiating ACE inhibitor treatment can be considered in DPs with occult CM. We use carvedilol (Coreg, SmithKline Beecham) at 12.5mg every 12 hours orally for 1 week and then 25mg every 12 hours orally because it may be the most effective β -blocker in humans with CM. Carvedilol is also a vasodilator (α -blockade) and a potent antioxidant, and it has anti-endothelin activity. The drug is expensive currently. A dosage of 25mg every 12 hours produces blood levels that are associated with mild-to-moderate β -blockade in DPs, depending on patient size. After 2 additional weeks an increase to 37.5mg every 12 hours is recommended in patients greater than 35kg. In spite of its α -blocking (afterload reducing) activity, carvedilol embarrasses contractility if myocardial failure is severe. It is critical that high doses of carvedilol *not* be initiated in DPs with overt or impending CHF. For example, DPs with overt CHF and sinus rhythm sometimes cannot tolerate a starting dosage of 3.125mg every 12 hours, and those with CHF and atrial fibrillation may not tolerate even 1.56mg every 12 hours. However, overt adverse affects are uncommon if the fractional shortening is greater than 18%. The dosage of carvedilol may need to be adjusted downward should severe CHF occur.

These regimens are based on the pathophysiology of CM and the success of these medications in humans. Extrapolating data from human studies and applying it to dogs are often inappropriate. We have not observed an obviously favorable influence of carvedilol or spironolactone on disease progression. A large randomized prospective study is needed.

At least 30% of DPs with CM eventually experience life-threatening ventricular ectopy. Such an incidence would seem to dictate aggressive therapy. However, most antiarrhythmic drugs have proarrhythmia activity, some are negative inotropes, and sustained efficacy has not been proven. In addition, adverse effects, mostly gastrointestinal disturbances, are common. Although SD in DPs with occult CM can be retarded, it probably cannot be prevented. Criteria for initiating antiarrhythmic treatment are controversial. We initiate treatment for:

1. Rapid (>200 beats/min) VT (Lown class 4)
2. Syncope with subsequent documentation of many VPCs (presumed Lown class 4)
3. Couplets or triplets of VPCs (Lown class 3) with greater than approximately 6000 to 8000VPCs/24 hours.

A standard ECG and even a 24h Holter ECG are short samples-in-time. Frequent (at least every 3 months) Holter recordings should be performed in affected dogs when possible because of the dynamic and progressive

nature of arrhythmias in many DPs. In the face of refractory rhythm disturbances, Holter recordings may need to be repeated at 1- to 4-week intervals until the rhythm is stabilized. Because of the high risk of SD, some veterinarians prefer to treat all affected DPs presenting with VPCs or VT.

In therapy of ventricular ectopy we recommend mexiletine (Mexitil, Boehringer Ingelheim) at 5 to 6 mg/kg every 8 hours orally for maintenance treatment. Mexiletine frequently causes gastrointestinal upset, but this may be significantly reduced if each dose is given with a small amount of food. If the patient is not already being administered carvedilol, initiate it at this time (if CHF is neither present nor imminent) since the combination of a β -blocker and mexiletine is more effective (in the short-term) than either alone. Rapid and remarkable improvement in VT severity is usual following the initiation of mexiletine. However, in spite of treatment at least 50% of the ventricular arrhythmias in DPs with occult CM become refractory within 3 to 9 months. Under these circumstances consider the addition of amiodarone (10 mg/kg q12h PO for 5 days and then 5 mg/kg q24h PO). Initial follow-up Holter recordings in DPs administered amiodarone sometimes document improvement in the severity of VT, but long-term efficacy has not been proven, and all of the DPs that we have treated with amiodarone have died suddenly. Whether amiodarone exerts a favorable, unfavorable, or neutral effect on time to SD has not been determined. Amiodarone is associated with numerous adverse effects in humans. Even in large DPs we have consistently encountered gastrointestinal disturbances and reversible hepatotoxicity at a maintenance dosage of 400 mg once daily. A maintenance dosage of 200 mg once daily sometimes causes hepatotoxicity. Baseline, 1 week, and then monthly serum chemistry profiles are required.

As myocardial failure worsens, a positive inotrope should be considered. Pimobendan (Vetmedin, Boehringer Ingelheim) administered at 0.3 mg/kg every 12 hours orally is a potent inodilator that exerts a significant positive inotropic action in DPs with advanced CM. We do not recommend pimobendan in dogs with fractional shortening values of 20% or greater. Of major concern is the protracted administration of a powerful positive inotrope in patients with myocardial disease. Past experiences with such drugs have been unfavorable in dogs and humans because of increased SD risk. We have encountered worsening of VT and SD in some DPs treated long term with pimobendan. However, to be determined is whether SD risk in DPs administered pimobendan is greater than in those not administered pimobendan. In one study of overt CHF, pimobendan was associated with prolonged survival in DPs with CM (Luis Fuentes et al., 2002).

We do not recommend digoxin for the treatment of CM in DPs except in the face of atrial fibrillation or sustained or frequent paroxysmal atrial tachycardia. In addition, we do not recommend furosemide treatment until CHF is imminent. Furosemide is used when patients develop nocturnal dyspnea, a gallop heart rhythm, or distended pulmonary veins or based on echocardiographic measurements of high preload.

Myocarditis

KARSTEN E. SCHOBER, *Columbus, Ohio*

Myocarditis is one of the most challenging diagnoses in small animal cardiology and may be even more difficult to manage. The entity is rarely recognized clinically, the prevalence unknown and probably underestimated, the pathophysiology poorly understood, and the clinical presentation and course variable. Furthermore there is no commonly accepted diagnostic gold standard, and all current specific treatments are controversial.

Myocarditis is defined as an insidious inflammatory disorder of the myocardium characterized by leukocytic infiltration and nonischemic myocyte degeneration and necrosis (Feldman and McNamara, 2000). Because there is no consistently recognizable clinical syndrome or specific noninvasive diagnostic test, the clinical diagnosis of both acute and chronic myocarditis remains problematic and is often only presumptive. There are a variety of causes; infectious agents seem most relevant. Primary myocarditis is presumed to be caused by an acute viral infection or a postviral autoimmune response, neither of which are well studied in dogs or cats. Secondary myocarditis is inflammation caused by a specific pathogen, including bacteria, protozoa, fungi, drugs, chemicals, physical agents, and systemic inflammatory diseases. The causal link between active, viral myocarditis and the subsequent development of dilated cardiomyopathy (DCM) is documented in humans but much less appreciated and explored in small animals. This chapter briefly considers some of the current ideas regarding the manifestations, potential importance, and management of myocarditis in dogs and cats.

PATHOPHYSIOLOGY

Myocarditis has both infectious and noninfectious causes (Table 177-1). Cardiotropic viruses, including those with ribonucleic acid (RNA) and deoxyribonucleic acid cores, are the predominant pathogens that lead to myocardial inflammation in humans (Feldman and McNamara, 2000). Current speculation is that 10% to 30% of human myocarditis is virus associated. However, with the exception of canine parvovirus, the importance of viruses in the development of myocarditis is largely undetermined in dogs and cats.

Current knowledge of the pathogenesis of viral myocarditis stems mostly from laboratory animal studies. A viral infection of the heart follows a standard progression. Most viral pathogens enter the body through the upper respiratory or gastrointestinal tracts. Genetic susceptibilities that alter the autoimmune response to viral infections may be important at this stage. The *acute phase* (days 0 through 3; viremic phase; fulminant myocarditis) is characterized by systemic viremia, virus

binding to myocyte coreceptors, virus invasion into cardiomyocytes, and virus replication causing myocytolysis. Macrophage activation leads to the production and release of proinflammatory cytokines, including tumor necrosis factor (TNF), interferon- γ , various interleukins, and inducible nitric oxide (iNO). The *subacute phase* (days 4 through 14; inflammatory phase; postviral or lymphocytic myocarditis) is characterized by clearance of the viruses by natural killer cells, cytokines, perforin, and neutralizing antibodies. Attracted by cytokine release, mononuclear cells such as cytotoxic T and B lymphocytes enter the myocardium and may cause extensive cellular damage. By the end of this stage the virus has already been cleared from the body, but the ongoing immune response mediates the myocardial damage and cell death. In the final or *chronic phase* (days 15 and beyond; healing phase; chronic myocarditis) there is evidence of myofiber dropout and replacement fibrosis. Most patients recover completely. However, in others viral persistence and host-pathogen interactions lead to chronic inflammation, repetitive cycles of myocardial injury and repair, apoptosis, coronary microvascular spasm, and autoimmune effects. These responses can result in continued myocardial injury and slow evolution to DCM and heart failure. This may occur even after many years, and some cases of idiopathic DCM in dogs and cats may represent unrecognized viral myocarditis.

Slow-growing nonviral agents such as *Trypanosoma cruzi* may also cause chronic myocarditis with progressive DCM-like pathology after a prolonged latent period (Bonagura, 1995, p 850). Cardiotoxic drugs and drug hypersensitivity reactions have been associated with myocarditis. The severity of histopathologic lesions resulting from any of these agents varies with the severity of the insult and the nature and magnitude of the host-toxin interaction. Cardiac injury and myocarditis in critically ill patients is often severe but remains most commonly unrecognized. Potential mechanisms for myocarditis in such patients include excess NO and proinflammatory cytokine production, endotoxins, direct bacterial damage, and ischemia and reperfusion. Traumatic injury of the heart caused by nonpenetrating chest trauma (referred to as *traumatic myocarditis*) may be associated with myocardial contusion, intramyocardial bleeding, inflammation, and myocardial degeneration and necrosis. Myocardial dysfunction is a rare consequence and almost always reversible, and arrhythmias are usually benign. There is no evidence of long-term myocardial damage and dysfunction after traumatic myocarditis in dogs and cats (Bonagura, 1995, p. 846).

Table 177-1

Causes of Myocarditis in Dogs and Cats

Infectious	Viral (parvovirus,* distemper virus,* herpesvirus, coronavirus, others) Bacterial* (various) Rickettsial (<i>Rickettsia</i> , <i>Ehrlichia</i> , <i>Bartonella</i> *) Spirochetal (<i>Borrelia</i> ,* <i>Leptospira</i> *) Fungal (various) Algae-like (<i>Prototheca</i>) Protozoal (<i>Trypanosoma</i> ,* <i>Toxoplasma</i> ,* <i>Neospora</i> , <i>Hepatozoon</i>) Parasitic (<i>Toxocara</i> , <i>Trichinella</i>)
Physical	Traumatic chest or body impact Hyperthermia
Immune-mediated	Postinfectious Systemic disorders Drug hypersensitivity
Toxic	Drugs Toxins
Other	Idiopathic

*Most commonly described.

PATHOLOGY

Inflammation may cause the myocardial pallor with occasional areas of minute hemorrhage. Microscopically there is distortion of muscle fibers caused by interstitial edema and fiber necrosis. The inflammatory infiltrate is usually lymphocytic. Morphometric quantification of the lesions is essential, with 14 leukocytes/mm² being the cutoff to distinguish between the presence and absence of myocarditis in humans. Immunohistochemical staining for T lymphocytes may be needed to establish the diagnosis. Depending on the causative agent, there may be more specific histologic features. Healing is often associated with interstitial fibrosis. A viral origin of myocarditis can only be proved if viral particles such as inclusion bodies or the virus itself are detected within an altered myocardium. This has become possible through molecular analysis of necropsy and endomyocardial biopsy specimens using new techniques of viral gene amplification, including polymerase chain reaction (PCR) and in situ hybridization. The *histologic* diagnosis of myocarditis was clarified by the Dallas criteria (see the following section on Clinical Manifestations and Diagnosis), but these unfortunately did not include immunohistochemistry to demonstrate a T cell-mediated immune response. The *clinicopathologic* classification of primary myocarditis originally proposed by Braunwald and associates is based on the onset of illness, left ventricular function, endomyocardial biopsy (EMB) findings, and clinical and histologic outcomes and led to four classes of myocarditis: fulminant, subacute, chronic active, and chronic persistent. This classification has not yet gained wide acceptance in veterinary medicine.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Myocarditis can create diverse clinical features. The diagnosis of acute myocarditis is made largely by clinical

history and a high index of suspicion rather than a definitive diagnostic test. It may follow upper respiratory or gastrointestinal infection, surgery, or recent drug exposure. General constitutional symptoms, particularly fever, anorexia, soft cough, muscle pain, exercise intolerance, and diarrhea, are often reported. There is no specific *clinical sign* on which to base the diagnosis. Classically the combination of an acute infective illness and myocardial abnormalities such as a sudden onset of unexplained ventricular arrhythmia, syncope, episodic weakness, acute congestive heart failure (CHF), anesthetic death, or sudden death may suggest the diagnosis. Thoracic auscultation may disclose evidence of an arrhythmia, a cardiac murmur, or abnormal lung sounds such as crackles.

Electrocardiography may reveal a variety of findings, including persistent sinus tachycardia, ST segment, QT and T wave abnormalities, ventricular or supraventricular ectopy, and atrioventricular (AV) conduction disturbances, including complete AV block (Kaneshige et al., 2007). Although such electrocardiogram (ECG) findings are nonspecific, the ECG has the virtue of drawing attention to the heart and leading to echocardiographic and other investigations.

Radiography may be unremarkable or reflect cardiomegaly, venous congestion, and pulmonary interstitial and alveolar densities suggestive of CHF or pulmonary infection. As with other noninvasive techniques, *echocardiography* may be unremarkable or display nonspecific findings. Diffuse or focal nodular thickening and heterogeneous granular texture of the myocardium caused by cellular infiltrates and pericardial effusion have been observed in association with acute (or fulminant) myocarditis. Segmental or generalized ventricular wall motion abnormalities and hypokinesis have been reported in humans and cats with histologically proven myocarditis. However, such changes may be confused with abnormalities caused by myocardial ischemia or infarction. The most important aspect of echocardiography may be its ability to exclude other types of myocardial and valvular heart diseases.

Laboratory tests, including the analysis of serum cardiac troponin (cTn) concentration, is a promising approach to specifically diagnose acute myocardial injury. Unfortunately blood cTn is not altered consistently in myocarditis, nor is it specific of myocardial inflammation. In addition, the window for diagnosis may be relatively brief. Nevertheless, elevation of serum cTn in association with a strong clinical suspicion may aid in the early presumptive diagnosis of acute myocarditis in which significant myocytolysis and myocardial necrosis may occur (Fig. 177-1). Experimental studies in mice (Smith et al., 1997) and clinical studies in humans (Lauer et al., 1997) with histology-proven myocarditis reported on the high sensitivity of cTn in the diagnosis of acute myocarditis and the close relationship between serum concentrations of cTn and the severity of myocardial inflammation. The value of cTn in the diagnosis of chronic myocarditis is limited. *Serologic testing* for known infectious causes (including toxoplasmosis, borreliosis, rickettsial diseases, bartonellosis, and Chagas' disease) may identify the causative antigen and assist in further treatment plans.

EMB continues to be the most definitive test and gold standard to confirm myocarditis in vivo in humans; but it

Fig. 177-1 Serum cardiac troponin I (cTnI) concentration in 60 dogs with the clinical diagnosis of acute myocarditis. Diagnostic criteria were the sudden onset of unexplained ventricular or supraventricular ectopy, abnormal diffuse or focal thickening of the left ventricle with granular texture of the myocardium on two-dimensional echocardiography, left ventricular systolic dysfunction with no or only minor chamber dilation, or vegetative endocarditis associated with ventricular tachyarrhythmias. Dogs with known structural heart disease (congenital and acquired), recent trauma, a splenic mass, and gastric dilation-volvulus syndrome were excluded. Open circles represent dogs with acute myocarditis confirmed by histopathology. Zero cTnI refers to the lower limit of detection of the immunoassay used (0.1 ng/ml; OPUS Troponin I, Dade-Behring Diagnostics Inc.). (From the veterinary medical data base of the Department of Small Animal Medicine, University of Leipzig, Germany (unpublished data).)

is used infrequently in small animals because of its invasive nature, limited sampling access, small sample size, relevant interobserver variability in the histologic assessment of the sample, and relatively low diagnostic yield. The diagnosis depends on the presence of inflammatory infiltrates and myocyte degeneration or necrosis. To standardize the histologic diagnosis of myocarditis in human- (and animal)-model EMB specimens, the Dallas criteria were introduced by Aretz and colleagues in 1987. Such criteria distinguish between *active* myocarditis (presence of lymphocytes and myocytolysis), *borderline* or ongoing myocarditis (lymphocytic infiltration and absence of myocytolysis), and *negative* findings (absent lymphocytic infiltrates and myocytolysis). Since EMB does not appear to be a reliable method for making the diagnosis of myocarditis, biopsy is usually reserved

for refractory cases. Interestingly, PCR of tracheal aspirate samples looking for viral RNA has correlated highly with EMB results in humans and seems to be an alternative to EMB in situations in which acute viral myocarditis is suspected.

MANAGEMENT PRINCIPLES

The treatment of myocarditis is controversial, and no generally applicable therapeutic regimen has been established. Supportive care directed toward alleviating clinical signs is the first line of therapy. Specific aims of management are to stabilize cardiac pump function and reduce the risk of progression to heart failure, manage arrhythmias, and identify and remove infectious or toxic agents. There is good evidence from animal work that exercise in the setting of acute myocarditis is detrimental and therefore should be restricted. If an infectious cause can be identified or is suspected, it should be treated aggressively with effective antimicrobials. In patients with symptoms of heart failure, medical therapy should focus on reduction of cardiac load, improvement of ventricular pump function, suppression of exaggerated neuroendocrine activation and arrhythmias, and long-term cardiac protection. Treatment options include diuretics, angiotensin-converting enzyme (ACE) inhibitors, positive inotropes, spironolactone, and β -adrenergic blocking agents once clinical stability has been achieved.

There is evidence from murine models that commonly used drugs for the treatment of CHF may have additional beneficial and more specific effects in acute myocarditis. The following treatments might be useful based on extrapolation from models. ACE inhibitors have been shown to directly decrease the amount of myocardial inflammation. Cytokine activation secondary to the inflammatory process results in the stimulation of nitric oxide synthase and the production of excessive amounts of NO from injured myocytes. This effect may be blunted with the positive inotrope pimobendan (Vetmedin, Boehringer Ingelheim) (0.2 to 0.3 mg/kg orally [PO] q12h) and the calcium channel antagonist amlodipine (Norvasc, Pfizer). In contrast, digitalis may increase the myocardial production of proinflammatory cytokines, induce vascular spasm, worsen myocardial injury, induce arrhythmias, and increase mortality in viral myocarditis. Therefore digoxin should be avoided or only used with extreme caution. β -Blockade may decrease the extent of myocardial damage and improve survival, presumably by relief of coronary vasospasm. Propranolol, sotalol, and carvedilol are preferred because of their nonselectivity. Hemodynamically relevant arrhythmias occur frequently and necessitate antiarrhythmic treatment (see section on Arrhythmogenic Right Ventricular Cardiomyopathy later in the chapter). Arrhythmias are commonly labile in acute myocarditis; and both the type of arrhythmia and the underlying electrophysiologic mechanism may change quickly. In addition, effective doses of antiarrhythmics are difficult to predict in dogs and cats with acute myocarditis and are often substantially different from commonly recommended doses. Occasionally dogs and cats with myocarditis need temporary or permanent cardiac pacing for AV block to achieve hemodynamic stabilization and relief of clinical signs.

A variety of new therapies for myocarditis are available in humans, including antiviral agents and vaccines, immunosuppression, and modulation of the biologic response to inflammation. The specific question for patients with myocarditis is whether regimens designed to reduce or eliminate inflammation can provide clinical benefits compared to conventional heart failure therapy. A number of agents, including nonsteroidal antiinflammatory drugs, intravenous immunoglobulin, methylprednisolone, cyclosporine, azathioprine, antiviral drugs, and anti-TNF, have been used to treat acute myocarditis in humans and experimental animals. However, results of recent randomized, placebo-controlled human trials have failed to demonstrate beneficial effects of immunosuppression. Moreover, nonsteroidal antiinflammatory drugs may be detrimental because they may reduce viral clearance, attribute to an exaggerated cytotoxic response, induce coronary vascular spasm, and delay myocardial repair (and many are toxic to dogs and to cats) (Meune et al., 2003). The future development of effective treatment will depend on early diagnosis and detailed knowledge of the pathogenesis of myocarditis and subsequent immune response.

FELINE MYOCARDITIS AND CARDIOMYOPATHY

The incidence of myocarditis in cats is largely unknown. However, there is some evidence that acute endomyocarditis (EMC) may be of particular importance in the cat. In a series of 461 cats with cardiomyopathy first published by Liu in 1977 and later summarized in his review of cardiomyopathy (Liu, 1985), about 6% were diagnosed with EMC. Affected cats were young, with a mean age of 2.6 years (range 2.5 months to 8 years). Most cats (85%) with acute myocarditis died suddenly. Some cats were dyspneic and depressed and had leukocytosis for 1 to 2 days before death. In another retrospective study considering 1472 feline necropsies performed over a 7-year period, Stalis, Bossbaly, and Van Winkle (1995) reported on 37 (2.5%) cases of EMC and 25 (1.7%) cases of left ventricular endocardial fibrosis. Four (0.3%) cats had histologic evidence of both diseases. Similar to Liu's study, cats with EMC were young (mean age at death 3.4 years, range 6 months to 14 years). Interstitial pneumonia was found in 71% of cats with EMC. Based on such studies it seems that antecedent respiratory infections and stress are potential precursors of EMC in cats and that restrictive cardiomyopathy and left ventricular endocardial fibrosis represent one late sequel to EMC (Stalis et al., 1995). Therapy of EMC in cats is symptomatic, mainly for CHF.

Arrhythmogenic Right Ventricular Cardiomyopathy

Arrhythmogenic right ventricular cardiomyopathy (ARVC), a newly described myocardial disease in cats (Fox et al., 2000), is also characterized by a high incidence of myocarditis reaching 83% of affected cats in a small case series. Of note, the histopathologic changes of ARVC were not confined to the right ventricle. Similar but generally less marked lesions of myocardial injury and repair were also observed in the ventricular septum or the left ventricular free wall of most animals. However, the possible pathogenic role of myocardial

inflammation as a potential injury mediator in ARVC is still undetermined. Conventional heart failure therapy with furosemide, enalapril, and nitroglycerin and antiarrhythmic treatment with atenolol, sotalol, or procainamide are recommended. In the near future the use of pimobendan for inotropic support of the failing heart may be an additional treatment option in cats with ARVC and heart failure.

Toxoplasmosis

Toxoplasmosis is a common but largely underappreciated cause of myocarditis in cats. Two case series of *Toxoplasma gondii*-infected cats (Dubey et al., 1993, 1996) revealed myocarditis in 62.7% and 100% of the animals by histopathology. However, there is only one single published report on the antemortem diagnosis of toxoplasmosis in a cat (Simpson et al., 2004). Oral clindamycin (8mg/kg q8h or 12mg/kg q12h PO) is the treatment of choice to clear the infection.

Transmissible myocarditis and diaphragmitis (TMD) has been described in cats in northern California. Clinical signs included transient fever, depression, lethargy, and lymphadenopathy (Pedersen et al., 1993). All cats had histology-proven acute myocarditis and diaphragmitis characterized by small pale foci within the myocardium, intramyocardial hemorrhage, myonecrosis, and mononuclear cell infiltrates. A causative organism could not be identified.

MYOCARDITIS IN THE DOG

As with cats, the incidence of myocarditis in the general canine population is unknown. However, very similar to cats, a retrospective necropsy study, including 4638 consecutive dogs seen in the pathology department over a 9-year period at a European Veterinary Teaching Hospital, reported on 70 (1.5%) dogs with the histopathologic diagnosis of myocarditis (Venzin et al., 1990). Dyspnea was the most often encountered clinical sign, and arrhythmias occurred frequently, but sudden cardiac death was rare (4.2%). Inflammatory lesions were found equally distributed between both ventricles. Myocarditis was judged as primary in 33% and secondary in 67% of dogs and was suppurative in 67% of cases. Canine distemper, toxoplasmosis, leptospirosis, and leishmaniosis were the most often determined causes of secondary myocarditis.

Parvovirus. Parvovirus myocarditis was an extensive problem in young puppies in the late 1970s and early 1980s, when the virus first appeared. Sudden cardiac death or acute death secondary to pulmonary edema was common. Apparently some dogs survived the neonatal infection and developed a disease clinically indistinguishable from DCM. Histopathologic characteristics were myofiber loss, myocytolysis, and lymphocytic and plasmacytic infiltrates (Liu, 1985). Large, basophilic intranuclear inclusion bodies found in the myocardium of acutely infected puppies were pathognomonic findings. No cases of parvovirus-induced myocarditis have been identified in the canine literature since the early 1980s.

Chagas' disease. Chagas' disease is a leading cause of myocarditis and myocardial failure in humans and dogs in Latin America. It is a rare disease in North America and is caused by *T. cruzi*, a hemoflagellate protozoon parasite (see Bonagura, 1995, p 850).

Lyme disease. Lyme carditis is a rare cause of myocardial disease in dogs. It is caused by infection with the spirochete *Borrelia burgdorferi*. Classically AV block, including complete heart block, is seen; but ventricular arrhythmias and myocardial failure occasionally occur. If Lyme carditis is suspected, diagnosis can be confirmed by antibody titers. The efficacy of antibiotic therapy (intravenous penicillin G and tetracycline) in Lyme carditis associated with AV block is not established. Symptomatic dogs with AV block may require temporary or permanent cardiac pacing.

Bartonellosis. Severe multifocal myocarditis and valvular endocarditis secondary to *Bartonella vinsonii* ssp. *berkhoffi* infection has recently been described in dogs. Diagnosis was based on seroreactivity to *B. vinsonii* antigens as determined by immunofluorescent assay testing. Conventional blood cultures generally failed to result in bacterial growth. Treatment with enrofloxacin, doxycycline, and azithromycin should be attempted; however, complete elimination of the infection may be difficult to attain.

Atrial myocarditis. A particular form of cardiomyopathy that preferentially destroys the atrial myocardium has been observed in dogs, most commonly in English springer spaniels. Myocardial destruction is most likely the result of a myocarditis of unknown etiology. Atrial standstill, a nodal escape rhythm, and complete AV block are observed frequently. The atrial cardiomyopathy may be followed by ventricular myocardial failure. Treatment includes permanent cardiac pacing and symptomatic medical therapy, including furosemide, spironolactone, an ACE inhibitor, and pimobendan. Long-term prognosis is poor because CHF or sudden death occurs early.

Arrhythmogenic right ventricular cardiomyopathy. As in cats, ARVC is associated with myocarditis in almost two thirds of cases, frequently affecting both the right and left ventricles. Because myocarditis was conspicuously present in all ARVC dogs with sudden cardiac death in one study (Basso et al., 2004), it is assumed that myocardial inflammation may also play a role in arrhythmogenesis. Therapy with class III antiarrhythmics, preferentially

sotalol at 1.5 to 3.5 mg/kg every 12 hours orally, is the preferred treatment option. Alternatively the combination of mexiletine (4-6 mg/kg q8h PO) and sotalol or atenolol (12.5 mg/dog q12h PO) has been used (see Chapter 175). However, evidence is lacking that antiarrhythmic therapy prevents sudden cardiac death in dogs with ARVC. The minority of dogs with ARVC that develop CHF should be treated symptomatically.

Management of Feline Myocardial Disease

VIRGINIA LUIS FUENTES, *Hatfield, Hertfordshire, United Kingdom*

CLASSIFICATION OF MYOCARDIAL DISEASE

Ever since the descriptions of cardiomyopathy in cats in the early 1970s, the management of feline myocardial disease has been complicated by problems in distinguishing the different forms of myocardial disease. Although echocardiography has become the standard for recognition and staging of cardiomyopathy (Table 178-1), often the situation is not straightforward. Using the WHO classification of human cardiomyopathies as a basis for feline myocardial disease, feline cardiomyopathies were originally categorized as hypertrophic, dilated, restrictive, or unclassified, with the subsequent addition of arrhythmogenic right ventricular cardiomyopathy. However, the exact classification of the disease in individual cats has continued to be challenging, particularly since end-stage disease can result in a phenotype that does not fit comfortably in any category except “unclassified.”

The problems of a classification with anatomic, functional, and etiologic roots have recently been addressed in a scientific statement by the American Heart Association (Maron et al., 2006). Human cardiomyopathies are now divided into primary (in which the myocardial changes are the major abnormality such as hypertrophic cardiomyopathy) and secondary (in which a multiorgan systemic disease such as hyperthyroidism also affects the myocardium). Primary cardiomyopathies are divided into those with a genetic basis, those with an acquired etiology, or those with a combination of genetic and acquired factors (mixed). Hypertrophic cardiomyopathy (HCM) and arrhythmogenic cardiomyopathy are considered genetic in humans, whereas dilated cardiomyopathy (DCM) and restrictive cardiomyopathy (RCM) are classed as mixed. There is now firm evidence that HCM can be genetic in cats: two separate mutations in myosin-binding protein C have been documented in Maine coons and rag dolls with HCM. There is also evidence that DCM can be acquired in cats with taurine-deficient diets. Nevertheless, in the majority of feline cardiomyopathy cases, we can only guess at the etiology. Cats are also affected with secondary cardiomyopathies such as hyperthyroidism and systemic hypertension, which commonly affect myocardial function.

To add to these difficulties in classification, cats may progress from one phenotype to another. Myocardial infarction can complicate HCM, RCM, or DCM, resulting in regional wall thinning and hypokinesis irrespective of the original left ventricular (LV) morphology.

An end-stage form of HCM has also been described in human and feline patients, characterized by LV hypertrophy with dilation and reduced systolic function. Even on a genetic level, some mutations can be characterized by a DCM or HCM phenotype; thus it is no surprise that some feline patients are difficult to classify.

For those who manage cats with myocardial disease in practical settings, it may be more important to stage the disease in individual cats rather than agonize over the correct classification of the type of cardiomyopathy. Asymptomatic cats with myocardial disease require different management from those with congestive heart failure (CHF). Table 178-2 outlines the use of different therapies according to the stage and type of cardiomyopathy. Specific clinical problems include distinguishing asymptomatic cats with HCM from cats with functional murmurs and distinguishing cats with CHF caused by myocardial disease from those with other causes of respiratory distress.

APPROACH TO THE ASYMPTOMATIC CAT WITH A MURMUR

The prevalence of murmurs in the healthy cat population is high, and many of these murmurs are probably associated with HCM (Côté et al., 2004). However, the finding of a murmur is never an indication for empiric therapy for heart disease. Some cats have low-to-moderate intensity systolic murmurs associated with high cardiac output and adrenergic states associated with anemia, hyperthyroidism, or fever. Other causes of sympathetic activation (stress, drugs) can be associated with a systolic murmur in healthy cats, and the murmur sometimes seems related to a hyperdynamic contraction of the right or left ventricle. Other disorders that may be associated with heart murmurs include systemic hypertension, congenital heart defects, and idiopathic aortic dilation. A significant number of cats have no obvious anatomic or physiologic cause of a heart murmur (functional murmurs).

A good clinical workup considers each of these diagnoses; but once hyperthyroidism and anemia (high cardiac output states) have been ruled out, further diagnostics are usually necessary. A normal cardiac silhouette on radiographs does not rule out cardiomyopathy, but it is a good indication that minimal structural changes are present (i.e., the murmur is functional, or LV hypertrophy is mild). The six-lead electrocardiogram (ECG) probably has relatively good specificity for heart disease, but the sensitivity seems too low since many cats with structural heart

Table 178-1

Two-Dimensional and M-Mode Echocardiographic Characteristics of the Main Feline Cardiomyopathies

	Normal	Hypertrophic Cardiomyopathy	Restrictive Cardiomyopathy	Dilated Cardiomyopathy	Arrhythmogenic Right Ventricular Cardiomyopathy

FS%, LV fractional shortening; IVSd, interventricular septal thickness in diastole; LA, left atrial; LA:Ao, left atrial:aortic diameter in two-dimensional echocardiographic short-axis view; LAx, right parasternal long-axis view; LV, left ventricular; LVDd, LV diameter in diastole; LVDs, LV diameter in systole; LVFWd, left ventricular free wall thickness in diastole; LVOT, LV outflow tract; RA, right atrial; RV, right ventricular.

disease have a normal ECG. Echocardiography certainly should be recommended if cardiomegaly is identified on radiographs or by analysis of the ECG. The NT-proBNP and NT-proANP assays also offer some promise as initial screening tests for cardiomyopathy (Feline Cardiacare, Veterinary Diagnostics Institute; Vetsign CardioSCREEN, Guildhay) since natriuretic peptide concentrations may be increased in asymptomatic cats with myocardial disease (Connolly et al., 2008), but echocardiography remains the gold standard for diagnosis of cardiomyopathy or exclusion of serious heart disease. The use of a cardiac troponin (cTnI) as a marker of myocardial injury has been suggested in a number of reports; but, as with natriuretic peptides, specific cutoffs for sensitivity and specificity require further study. Some standardization among laboratories and kits is also required if biomarkers are to be used effectively for diagnosis.

Table 178-1 lists a summary of echocardiographic features characteristic of the different types of cardiomyopathies. Echocardiography is useful to document dynamic outflow tract obstruction (LV or right ventricular) and the presence of LV hypertrophy. Echocardiography also can be used to assess risk of CHF, with left atrial (LA) dilation being a useful simple indicator of increased risk for CHF

and thromboembolism and transmitral flow and tissue Doppler imaging contributing to more sophisticated assessments. Although cats with mild asymptomatic disease are unlikely to require treatment, they are still at risk of developing CHF with interventions such as intravenous fluid therapy or anesthesia. It is unusual to diagnose RCM or DCM in asymptomatic cats; they more commonly present with CHF or arterial (aortic) thromboembolism (ATE).

MANAGEMENT OF ASYMPTOMATIC HYPERTROPHIC CARDIOMYOPATHY

Goals of therapy include prevention of CHF, ATE, and sudden cardiac death and the prevention or reversal of myocardial abnormalities, although it is far from clear how to achieve these goals. It may not even be necessary to aspire to these goals in all cats, since the prognosis for life appears very favorable in most cats without any therapy. Other asymptomatic cats clearly are at risk for CHF and ATE. LA enlargement and massive global or segmental LV hypertrophy (as opposed to focal thickening) are sometimes taken as predictors for these risks. However, objective risk factors for development of CHF, ATE, or fatal arrhythmia have not been well defined in prospective studies.

–, Not indicated; ±, no clear indication or indicated in selected cases; +, indicated; ACE, angiotensin-converting enzyme; ARVC, arrhythmogenic right ventricular cardiomyopathy; CHF, congestive heart failure; DCM, dilated cardiomyopathy; HCM, hypertrophic cardiomyopathy; HOCM, hypertrophic obstructive cardiomyopathy; RCM, restrictive cardiomyopathy.

Although regression of LV hypertrophy may be a desirable goal, the mechanisms of hypertrophy may be so diverse in different forms of HCM that one common therapeutic strategy may not be capable of achieving this result. Angiotensin-converting enzyme (ACE) inhibitors or angiotensin II antagonists, spironolactone, and statins have all been used successfully in experimental HCM models. However, in one prospective 12-month study of Maine coons with HCM, treatment with the ACE-inhibitor ramipril (0.5 mg/kg q24h orally [PO]) *failed to show any effect* on either LV hypertrophy or diastolic function (MacDonald et al., 2006).

The specific risk of ATE in asymptomatic cats with HCM has not been published. Most clinicians view LA enlargement as a likely risk factor for this complication, and many consider antithrombotic therapy appropriate in HCM cats with this echocardiographic finding. This treatment is discussed in the following paragraphs and in Chapter 180.

DRUG THERAPY CONSIDERATIONS IN ASYMPTOMATIC CATS

Although there might be value in treating asymptomatic HCM cats considered to be at high risk, there is no

consensus about which therapy should be used, and there are no published prospective studies demonstrating major end-point benefits of treatment. In situations in which either the owner or cat is reluctant to undertake lifelong medication, treatment remains difficult to justify (particularly if this is a source of daily stress for the patient). β-Adrenergic antagonists (atenolol), calcium channel antagonists (diltiazem), and ACE inhibitors each have their advocates. The use of these drugs in asymptomatic disease is based mostly on theoretic benefit or studies with relatively low-grade clinical evidence.

β-Blockers reduce myocardial oxygen consumption, an effect that should reduce demand ischemia. This benefit, along with slowing heart rate and prolonging diastolic filling, may have some overall benefit on diastolic function in HCM. Atenolol also reduces stress-related dynamic outflow obstruction (see following paragraph). The total daily dose of atenolol is generally 1 to 4 mg/kg daily, with some clinicians using a single dose and others preferring twice-a-day dosing. When twice-daily dosing is prescribed, the two doses may be unequal (e.g., ½ of a 25-mg tablet in the AM and ¼ of a 25-mg tablet in the PM). Liquid atenolol can be easier to dose than tablets. Many clinicians seem to dose atenolol to a heart

rate effect (e.g., to achieve a rate of 120 to 160/min during physical examination). Doppler echocardiography can be used to confirm that the dose of atenolol is sufficient to control outflow tract obstruction. Adverse effects of atenolol can include excessive bradycardia and cardiac dilation.

The calcium channel antagonist diltiazem may improve LV relaxation, although definitive evidence of this effect in cats is lacking. Diltiazem also slows heart rate and reduces dynamic outflow obstruction, although less consistently than atenolol. Standard diltiazem is dosed at 7.5 mg every 8 hours orally, which is impractical for most cat owners. Extended-release preparations of diltiazem permit once- or twice-daily dosing using preparations such as Dilacor XR (Watson Pharma, Inc.) at 15 to 30 mg every 12 to 24 hours orally. These long-acting diltiazem compounds can achieve therapeutic plasma levels; however, precise dosing guidelines are still needed for these drugs. Adverse effects of diltiazem include anorexia, weight loss, and skin lesions, with an overall incidence of side effects seemingly higher than with atenolol or ACE inhibitors.

Although ACE inhibitors have theoretic benefits in cardiomyopathy, there are no data supporting their use in asymptomatic cats. As cited previously, well-controlled studies in asymptomatic Maine coon cats have failed to show benefit of the ACE inhibition. However, I do consider an ACE-inhibitor for treatment of asymptomatic cats demonstrating LA enlargement. In theory vasodilation might worsen dynamic LV outflow tract (LVOT) obstruction unless a β -blocker or calcium channel blocker is also prescribed; however, the practical importance of this in cats is undetermined.

HYPERTROPHIC CARDIOMYOPATHY WITH DYNAMIC LEFT VENTRICULAR OUTFLOW TRACT OBSTRUCTION

In human HCM patients LVOT obstruction is associated with increased risk of heart failure and death (Maron et al., 2003). Control of LVOT obstruction is usually instigated when patients become symptomatic. In cats there is some controversy over the clinical significance of dynamic LVOT obstruction. One retrospective feline study suggested that systolic anterior motion of the mitral valve was associated with longer survival times (Rush et al., 2002). It is often possible to control dynamic LVOT obstruction with β -blockers in cats, and anecdotal evidence suggests that some apparently asymptomatic cats show an improvement in exercise tolerance or energy levels following administration of β -blockers. It is possible that symptomatic cats are more difficult to identify than symptomatic humans, particularly since human symptoms include signs such as chest pain. Cats with severe dynamic LVOT obstruction may be treated with atenolol and reexamined within the first month of treatment to confirm that LVOT obstruction has been controlled and no adverse effects have developed (such as bradycardia or an increase in LA size). The dose of atenolol can be titrated to a point at which the LVOT gradient has resolved (and the murmur has diminished or disappeared) without causing severe bradycardia.

SYMPTOMATIC CATS WITH CONGESTIVE HEART FAILURE: CLINICAL APPROACH

Physical examination findings that might arouse suspicion of myocardial disease with CHF include combinations of a systolic murmur, gallop sounds or arrhythmias with tachypnea, pulmonary crackles, and jugular distention. Sometimes no auscultatory abnormalities are present, although respiration is generally labored in inspiration and often in expiration. A prolonged inspiratory phase with noise should prompt consideration of upper airway obstruction. Prolonged expiratory efforts, especially with wheezing, are more suggestive of asthma or a fixed major airway obstruction. Crackles are a helpful finding for parenchymal disease but are not always evident. Muffled sounds ventrally may suggest pleural effusion or lung consolidation.

Imaging is critical to diagnosis. Radiography can be helpful for documenting pulmonary infiltrates or pleural effusion associated with CHF and excluding other causes of respiratory distress, although great care should always be taken when handling dyspneic cats. Sedation (butorphanol/butorphanol 0.1 mg/kg intramuscularly [IM], repeated to 0.3 mg/kg cumulative dose) may allow safer handling in stressed feline patients. These cats are very fragile, and thoracic ultrasound may offer a safer option for identifying pleural effusions in particular and perhaps the "comet tail artifacts" often related to pulmonary infiltration or edema.

Echocardiography is the only practical way of identifying the underlying structural and functional abnormality of the heart, and demonstration of LA enlargement can be extremely useful as a means of supporting a clinical suspicion of CHF. A full echocardiographic examination can always be delayed until the cat is more stable because characterization of the underlying myocardial disease is not crucial for initial management.

Additional diagnostic study should be accomplished as permitted by the clinical situation. Blood pressure should be measured. Routine laboratory tests (complete blood count, serum biochemistries), cytologic examination of effusions, and biomarker studies (troponin, natriuretic peptides) generally are indicated but may need to be delayed pending initial stabilization.

The differential diagnosis of CHF in cats includes other causes of respiratory distress, pulmonary infiltration, pleural effusion, or airway obstruction. Acute pulmonary infiltration with tachypnea can be associated with thoracic trauma, overinfusion of crystalloid, noncardiogenic pulmonary edema (see Chapter 150); severe pulmonary infections; lung parasitism (see Chapter 151); or spontaneous heartworm death (see Chapter 182). The two most common types of pleural effusions identified in cats with CHF are the modified transudate (with small lymphocytes in the cytology) and true chylothorax related to obstruction of systemic venous and lymphatic return. The differential diagnosis of pleural effusion is extensive and is considered in Chapter 153. Bronchial asthma in cats can be associated with acute dyspnea but is readily distinguished from CHF by examination and radiography (see Chapter 148). Uncommonly cats with dyspnea are found to have major airway obstruction related to nasopharyngeal polyps

(see Chapter 142 and Section VII on Evolve), laryngeal paresis (see Chapter 143), or tracheal obstruction.

MANAGEMENT OF THE SYMPTOMATIC CAT WITH CONGESTIVE HEART FAILURE

Short-term goals of therapy in cats with CHF include relieving life-threatening hypoxemia, lowering LA pressures, and improving hemodynamic function; improving hemodynamic function is particularly difficult in cats with diastolic dysfunction.

ACUTE CONGESTIVE HEART FAILURE

Fortunately the type of myocardial disease has less bearing on management than the stage of presentation. Oxygen, diuresis, and venodilation are all appropriate treatments for any cat with left heart failure. Pleural effusions must be drained if they cause respiratory distress, and this can be achieved with a 23-G butterfly cannula. Furosemide is the mainstay of treatment for cats presenting with acute pulmonary edema. Doses should be lower than those used in dogs, but some cats still require aggressive diuresis. For unresponsive cases intravenous furosemide at doses of 1 to 2 mg/kg can be repeated every 1 to 2 hours initially; but renal function, electrolytes, and blood pressure must be monitored. A constant-rate infusion of furosemide also can be considered (see Chapter 171). Topical 2% nitroglycerin cream (1/4 to 1/2 inch q8h) can be added for its potential venodilatory effect. Severely dyspneic cats must be handled with care, and stress should be avoided at all costs. Some cats benefit from low doses of butorphanol (0.1 mg/kg, repeated as needed) as sedation. Although ACE inhibitors may have some favorable venodilating effects, great caution should be used in cats with hypotension; and these agents are best avoided until systemic arterial pressures are at least 90 mm Hg.

LOW-OUTPUT HEART FAILURE

Some cats develop low output signs in addition to CHF. These cats typically present with hypothermia, bradycardia, and severe hypotension (systolic blood pressure <70 mm Hg). Although this is more common in RCM and DCM, some HCM cats may also present in this way, possibly related to acute ischemic events or myocardial infarctions. Traditionally positive inotropes are considered to be contraindicated in HCM because of the likelihood of increasing myocardial oxygen consumption. However, despite this admonition, dobutamine appears to be very effective in improving cardiac output and clinical signs in low-output cats irrespective of the type of underlying cardiomyopathy. Doses should be started at lower ranges than those used for dogs, with initial infusion rates of 1 to 2 mcg/kg/minute cautiously titrated upwards (to a maximum of 5 mcg/kg/min) over several hours. The therapeutic targets are improvements in systolic blood pressure to higher than 100 mm Hg, increase in heart rate, and normal body temperature, at which point the infusion can be maintained for 12 to 24 hours. Some cats show signs of nausea or restlessness with relatively low doses, and infusions exceeding 24 hours are rarely needed; the risk of

seizures become higher after 24 hours. Although dynamic LVOT obstruction is a definite contraindication to dobutamine, it is rarely evident during these low-output episodes, even in cats with HCM. Absence of a murmur makes LVOT obstruction especially unlikely. Warmth and supportive care are important; and, in the rare cases in which low output signs are present in the absence of CHF, it may even be necessary to consider cautious intravenous fluid therapy with low-sodium containing fluids.

HOME MANAGEMENT OF CONGESTIVE HEART FAILURE

Long-term goals of therapy include prevention of abnormal sodium and water retention, modulation of adverse neurohormonal activation, delay or reversal of myocardial changes, and prevention of thromboembolism. The first two goals may be achievable with oral furosemide and an ACE inhibitor alone in many cats. Furosemide should be titrated to effect (usually 1 to 3 mg/kg q8 to 24h PO), to achieve resolution of pulmonary edema and pleural effusions. Once congestive signs have resolved, the furosemide dose should be reduced as far as possible. Some cats suffer an acute episode of pulmonary edema but, once stable, remain well compensated for long periods with minimal doses of furosemide (and furosemide may even be withdrawn in a few cats). In hypotensive cats ACE inhibitors should be introduced cautiously, at quarter or half dose. Such cats often tolerate the full dose of ACE inhibitor in the long term but are vulnerable to worsening hypotension and azotemia following acute administration. ACE inhibitors do not appear to have an adverse effect on dynamic LVOT obstruction (Oyama, 2003) and should counteract adverse renin-angiotensin system (RAS) activation triggered by concurrent furosemide administration. There is no clear advantage of one ACE inhibitor over another; enalapril (0.25 to 0.5 mg/kg q24h PO), benazepril (0.25 to 0.5 mg/kg q24h PO), and ramipril (0.5 mg/kg q24h PO) all have been used. The individual types of cardiomyopathies may benefit from tailored therapy specific to the underlying functional disturbance.

Hypertrophic Cardiomyopathy

Asymptomatic cats *already receiving* diltiazem or atenolol can be treated with furosemide and an ACE inhibitor as listed previously in addition to the therapy they are already receiving. In some cases congestive signs may be easier to control if the β -blocker is withdrawn or at least reduced by 50%. Therapy with β -blockers should *never be started* while cats have any signs of CHF and are probably only indicated in cats with well-compensated HCM with obstruction. Spironolactone might have several theoretic benefits in cats with HCM and CHF since it has resulted in regression of LV hypertrophy in other HCM models and also helps to counteract RAS activation. However, spironolactone did not reduce fibrosis in a model of spontaneous feline cardiomyopathy, and a significant percentage of cats developed skin lesions with chronic administration (MacDonald et al., 2007). Overall spironolactone appears to be well tolerated and can be given as 1/4 of a 25-mg tablet per cat every 24 hours.

Dilated Cardiomyopathy

Oral taurine (250mg q12h) should be given to cats with global systolic dysfunction until plasma taurine concentration results are available. Genuinely taurine-deficient cats are now rare, but they have a good prognosis with taurine supplementation. Cats with idiopathic DCM are unlikely to show any response to taurine supplementation and have a much poorer prognosis. Digoxin traditionally has been given to cats with systolic dysfunction, but dosing can be problematic. Generally 1/4 of a 0.125-mg tablet is given every 48 hours for cats weighing less than 3kg; every 24 to 48 hours for cats weighing 3 to 6kg; and every 24 hours for cats over 6kg. Toxicity is common, and the hemodynamic benefits are not dramatic. The effects of pimobendan have not been studied in cats, but there are anecdotal reports of benefit in cats with systolic dysfunction using extralabel pimobendan (Vetmedin) at oral doses of 0.625 mg to 1.25 mg per cat every 12 hours orally.

Restrictive Cardiomyopathy

There is little in the way of specific therapy for either the myocardial or endomyocardial forms of RCM. Furosemide and an ACE inhibitor are standard therapy, but these cats are quite likely to become refractory to treatment and require additional diuretics (see following paragraph).

MANAGEMENT OF RECURRENT OR REFRACTORY CONGESTIVE HEART FAILURE

Furosemide can be titrated up or down to effect, but some cats have recurrent or persistent congestive signs. In the cat with progressive fluid accumulation it is reasonable to introduce spironolactone as an additional diuretic and neurohormonal modulator. Cats that become truly refractory to furosemide tend to lack both the beneficial and the adverse effects of furosemide such as azotemia. In these cases the dosage of furosemide and ACE inhibitors can be increased, or clients (if accepting) can be given preloaded syringes with furosemide (1 mg/kg) that can be administered subcutaneously two or three times weekly. An alternative is addition of a thiazide diuretic such as hydrochlorothiazide (1 to 2mg/kg q12 to 24h PO). This should be started without subtracting any of the prior therapy. Thiazides should be added at the lowest end of the dosage range and titrated up to effect with careful monitoring of renal function and serum electrolytes. Extralabel use of pimobendan (0.625 to 1.25 mg twice daily) is also potentially beneficial for these cats. Many cats with CHF can tolerate between 0.25 and 0.5mg/kg of enalapril or benazepril twice daily, and this may be another consideration. Periodic thoracocentesis or a brief hospitalization and parenteral diuresis may be needed for decompensation associated with marked dyspnea.

PROGNOSIS

There have been no prospective, multicenter, randomized trials of drug therapy of cats with CHF; and published data, although instructive, do not compare specific treat-

ment approaches or correct for client perceptions that may prompt euthanasia. Perhaps surprisingly to some, a 1-year or longer survival is not uncommon for a cat following the first bout of CHF provided there is good initial therapy, excellent home therapy, continuing veterinary support, and a willing owner. Many cats can tolerate small-to-moderate amounts of pleural fluid as long as they are not stressed; and clients can be taught to monitor respiratory rate and depth, activity, appetite, and attitude as markers of quality of life and control of CHF. Ultimately the combination of progressive CHF and advanced kidney failure tends to limit the success of these therapies. Other cases are complicated by ATE or sudden death.

ARTERIAL (AORTIC) THROMBOEMBOLISM

Cats with all forms of cardiomyopathy are at risk of ATE and this is particularly true of the more advanced stages of myocardial disease. Some cats present with an episode of ATE as their first sign of myocardial disease. Typically these cats have sudden onset signs of pain, vocalizing, and paresis when the aortic trifurcation is affected. Forelimbs can also be affected, sometimes with quick spontaneous recovery. Clinical signs may be more confusing with cerebral, mesenteric, or coronary embolism.

MANAGEMENT OF ACUTE THROMBOEMBOLISM

Affected cats are acutely distressed, and pain management is paramount. Epidural anesthesia is an ideal solution; otherwise opiates are necessary. Hypothermia is a poor prognostic sign and may be helpful in triaging which patients to treat. It can be difficult to distinguish tachypnea from pain versus CHF without radiography, and some cats die acutely in the first 24 hours from sudden hyperkalemia associated with reperfusion. There is still controversy over the risk-benefit ratio of thrombolytic therapy, and most clinicians opt for prevention of thrombus extension. Aspirin, unfractionated heparin (100 to 500 units/kg as an initial dose intravenously [IV]), and low-molecular weight heparin are all used. Supportive care is important, and confirmed concurrent congestive signs should be treated as described earlier. Management and prevention of ATE are discussed in Chapter 180.

PREVENTION OF THROMBOEMBOLISM

There is no consensus on the optimal therapy for prevention of aortic thromboembolism. Aspirin has been used for many years with a relatively low rate of side effects. Its efficacy has not been established, and a low-dose compounded dose (5mg/cat q3d) does not appear any less effective than a higher dose (81mg/cat q3d) based on retrospective analysis. Lower dosages do appear to have a lower rate of side effects (often related to gastrointestinal ulceration). Warfarin is associated with an unacceptable rate of side effects and an impracticably high level of monitoring requirements. Pimobendan is also said to have antithrombotic effects, which may be pertinent to cats receiving this drug for CHF therapy.

Clopidogrel (Plavix, 18.75 mg/cat q24h orally) offers some hope as a new antithrombotic treatment and is currently under evaluation (FATCAT trial). Clopidogrel shows in vitro inhibition of feline platelets and seems to be well tolerated, although ulceration is still a potential concern. Clopidogrel can be combined with aspirin, although it is probably safest to use the lowest aspirin dose (5 mg q3d) and to have clients monitor appetite as a marker of gastrointestinal side effects.

CHAPTER 179

Right Ventricular Cardiomyopathy in Cats

PHILIP R. FOX, *New York, New York*

OVERVIEW OF MYOCARDIAL DISEASE

Heart disease in the cat is caused principally by conditions that affect the myocardium. Cardiomyopathy describes a heterogeneous class of disorders, the dominant features of which are structural abnormality and functional impairment of the heart muscle (Fox, 1999). This excludes conditions resulting from valvular, hypertensive, vascular, pericardial, pulmonary, or congenital derangements. A variety of schemes have been proposed to define the cardiomyopathies. The term *idiopathic* (primary) cardiomyopathy has been applied classically to describe the myocardium as the sole source of heart disease when etiology cannot be identified; whereas *secondary* cardiomyopathy denotes heart muscle disease resulting from an identifiable systemic, metabolic, or nutritional disorder. This original classification has been expanded by The World Health Organization/International Society and Federation of Cardiology Task Force to include four types of idiopathic heart muscle disease (Richardson et al., 1996): hypertrophic, dilated, restrictive, and arrhythmogenic right ventricular cardiomyopathy (ARVC). Advancements in

echocardiography and the increasing affordability of this technology have increased clinical diagnostic reliability and awareness of these conditions.

INCIDENCE

Of the four types of idiopathic heart muscle disease in the cat, ARVC is the least common (Fox, 1999). In my cardiovascular clinic the prevalence of ARVC in cats examined by echocardiography is approximately 2% to 4%. Although still underrecognized, diagnosis of this disorder can be improved by rigorous application of diagnostic testing and appropriate clinical awareness.

ETIOLOGY AND PATHOGENESIS

ARVC has been described in dogs (Basso et al., 2004), humans (Nava, Rossi, and Thiene, 1997; Basso et al., 1996), and cats (Fox et al., 2000). Etiology and pathogenesis remain unresolved. Ventricular arrhythmias and ARVC are inherited as an autosomal-dominant trait in boxer

dogs (Meurs et al., 1999). In humans autosomal-dominant familial transmission has been reported, with a mutation identified at the cardiac ryanodine receptor 2 gene (Ryr2) in ARVC type 2 (Tisso et al., 2001; Rampazzo et al., 1994). In addition, autosomal-dominant and autosomal-recessive forms of human ARVC have been related to mutations in desmoplakin. Abnormalities in genes encoding for cell junctional proteins, including plakoglobin, desmoplakin, and plakophilin, are the focus of increasing attention (Sen-Chowdhry, Syrris, and McKenna, 2005; Gerull et al., 2004). Because desmosomes (organized intercellular junctions) lend cells mechanical integrity and stability, impaired function of cell adhesion junctions during shear stress may promote inflammation, myocyte detachment, myocyte death, and fibroplomatous repair (Thiene et al., 2005). Therefore ARVC increasingly has been considered to be a disease of the desmosome. Although I have noted familial tendencies of ARVC in cats, pedigree analysis is currently lacking. Neither the specific gene defects nor the defective coded proteins have been identified to date.

PATHOPHYSIOLOGY

Progressive atrophy of the right ventricular (RV) myocardium with fibrous and/or fatty replacement are common sequelae of ARVC in cats (Fox et al., 2000), dogs (Basso et al., 2004), and humans (Basso and Thiene, 2005). Gap junction remodeling secondary to altered mechanical coupling may promote arrhythmogenicity (Thienne et al., 2005). Abnormal myocardial structure and function are accelerated by myocarditis, programmed cell death, and fibrous and fatty infiltrates. Apoptosis is present in a high percentage of felines with ARVC (Fox et al., 2004), similar to that reported in humans (Valente M et al., 1998) and dogs (Basso et al., 2004). Both apoptosis and myocarditis in affected cats may contribute to myocyte injury and repair in susceptible felines. Atrophy of RV myocardium with fibrofatty replacement reduces cardiac reserve and provokes right-sided congestive heart failure (CHF). RV dilation and remodeling alter the geometry and function of the tricuspid valve apparatus and result in tricuspid valve insufficiency. The histopathologic changes of ARVC are not confined to the right ventricle, and similar but less marked lesions of myocardial injury and repair may be present in the ventricular septum or left ventricular (LV) free wall. This suggests that the ARVC disease process may progress over time to involve the left ventricle (Basso et al., 1996; Corrado et al., 1997).

SIGNALMENT

Right-sided heart failure is most frequently detected in middle-aged cats, although affected cats range in age from 1 to 20 years old. Currently there has been no documented gender predisposition. ARVC has been documented in many breeds; I have identified this condition most commonly in domestic shorthair and Birman cats.

CLINICAL PRESENTATION

Frequently the first clinical presentation is for CHF. Affected cats may show tachypnea, jugular venous distention, effusion

(pericardial, thoracic, abdominal), or hepatosplenomegaly. Right-sided heart failure is usually severe. Syncope has been documented with sustained ventricular tachycardia, but this finding is uncommon. Many cats are asymptomatic, and diagnosis is made during echocardiographic examination performed to assess a heart murmur or arrhythmia.

PHYSICAL EXAMINATION

Thoracic auscultation usually reveals a pansystolic heart murmur consistent with tricuspid regurgitation. This is often loudest along the right sternal or right costochondral border. Arrhythmias and associated femoral arterial pulse deficits may be detected. With right-sided heart failure affected cats may be tachypneic or dyspneic. Many of these animals have distended jugular veins, and some also have ascites and hepatosplenomegaly. The presence of pleural and pericardial effusion may cause heart and lung sounds to be muffled.

RADIOGRAPHY

Classic findings include enlargement of the right atrium and right ventricle. Often these changes are dramatic. Left atrial enlargement may be present in some cats. In cases with right-sided heart failure pleural effusion, ascites, hepatosplenomegaly, and cardiomegaly (often augmented by the associated pericardial effusion) may be present.

ELECTROCARDIOGRAPHY

A variety of arrhythmias have been documented, including supraventricular tachyarrhythmias (particularly atrial fibrillation); complex ventricular ectopy, including ventricular tachycardia (of RV and LV origin); and major conduction abnormalities. Ventricular tachycardia can be sustained in some cases. The frequency of atrial fibrillation is consistent with severe right atrial (RA) enlargement.

ECHOCARDIOGRAPHY

The most obvious echocardiographic finding is marked RV enlargement (Fig. 179-1). Abnormal RV muscular trabecular patterns (particularly in the apical cavity) are often a characteristic finding when coupled with RV dilation. Additional right heart changes include RA enlargement, paradoxical ventricular septal motion, and localized RV aneurysm formation (i.e., akinetic or dyskinetic areas with diastolic outward bulging) in the apical or subtricuspid region. Ventricular septal and LV wall thickness at end-diastole, LV end-diastolic and end-systolic cavity dimensions, and percent fractional shortening (in the absence of paradoxical septal motion) are generally within normal ranges. In some cats left atrial enlargement may be present. Doppler color flow imaging invariably demonstrates tricuspid regurgitation.

MAGNETIC RESONANCE IMAGING

Magnetic resonance imaging using T1 weighted images has demonstrated morphologic evidence of RV fatty infiltration in formalin-fixed ARVC hearts. When available, this technique may facilitate antemortem diagnosis.

Fig. 179-1 Echocardiograms from a cat with arrhythmogenic right ventricular cardiomyopathy. The right ventricle is severely dilated. RV, Right ventricle.

GROSS PATHOLOGY

Morphologic abnormalities are striking in feline ARVC (Fox et al., 2000). Typical findings include moderate-to-severe RV dilation; RV wall thinning (diffuse or segmental); flattened appearance of RV wall trabeculae; and prominent RV septo-parietal bands in the RV apex. Aneurysms in apical, subtricuspid, and infundibular regions of the RV wall may be small or extensive and appear translucent. Right atrial cavity dilation generally is present and severe, and segments of RA walls are markedly thinned. Mural thrombosis is observed occasionally in the right ventricle or left artery.

HISTOPATHOLOGY

The hallmark histopathologic feature of ARVC is partial or almost entire replacement of the RV free wall by fatty (25% of cases) or fibrofatty (75% of cases) tissue (Fox et al., 2000). These lesions closely resemble those characteristic of ARVC in humans and dogs. The fibrofatty pattern consists of focal or diffuse RV myocardial atrophy associated with adipose tissue and replacement-type fibrosis. The fatty pattern within the RV wall and trabeculae is characterized by multifocal or diffuse areas of adipose cell infiltration with only scant interstitial fibrosis (Fig. 179-2). Islands of myocytes are often surrounded by fat or fibrofatty tissue. In both forms residual surviving myocytes are usually scattered within the areas of fibrosis or fat, and fibro-fatty replacement usually extends from the epicardium toward the endocardium. Focal or multifocal RV myocarditis is most prevalent in ARVC cats with the

Fig. 179-2 Histologic section taken from a region of thinned, right ventricular wall in a cat with arrhythmogenic right ventricular cardiomyopathy. Myocardium is replaced by fatty tissue. Islands of residual myocytes are surrounded by adipocytes. (H&E stain, $\times 200$.)

fibrofatty pattern. It consists mostly of T lymphocytes associated with myocyte cell death and mild-to-severe fibrous tissue deposition. Similar findings may also be present in left and RA walls, the LV free wall, and the ventricular septum. Fatty infiltration is present occasionally in the LV free wall but not in the ventricular septum. Abnormal intramural small vessels with thickened walls (caused primarily by medial hypertrophy) are uncommon. Apoptotic myocytes have been identified by terminal dUTP nick-end labeling (TUNEL) histochemical investigation in 75% of affected cats.

DIFFERENTIAL DIAGNOSIS

Radiographic and echo-Doppler examinations provide a reliable assessment of cardiac structure and function and help differentiate other forms of heart disease, such as atrial septal defect. Feline ARVC is characterized by severe RV and RA dilation, and tricuspid valvular regurgitation is usually present. Consequently ARVC is invariably misdiagnosed as tricuspid valvular dysplasia. Congenital tricuspid valvular dysplasia, when severe, is usually apparent in the very young cat but rarely results in profound RV enlargement as occurs in ARVC. Also, tricuspid valve dysplasia is characterized by marked dysplasia of the tricuspid valve apparatus, including direct attachment of valve leaflets to papillary muscles and papillary muscle or valve leaflet fusion. These lesions are generally discernible by two-dimensional echocardiography. Other causes of RV dilation in the cat can be differentiated by careful echo-Doppler examination. RV enlargement can be present with pulmonic stenosis, tetralogy of Fallot or other causes of cyanotic heart disease, or pulmonary hypertension. However, such cases also have RV hypertrophy with other specific lesions. Because the left ventricle is generally unremarkable in ARVC cats, this condition cannot be confused with hypertrophic cardiomyopathy or endomyocardial fibrosis, two diseases characterized by distinctive LV alteration. Moreover, most cases of restrictive cardiomyopathy do not have the severe right heart dilation and RV wall thinning that typifies ARVC.

THERAPY

With right-sided CHF dyspnea may result from effusions, and prompt mechanical fluid removal (centesis) is indicated in such circumstances. Standard pharmacologic therapy for CHF includes diuretics, angiotensin-converting enzyme (ACE) inhibitors, and digoxin. Furosemide (2 to 6 mg/kg/day) and spironolactone ($\frac{1}{4}$ to $\frac{1}{2}$ of a 25-mg tablet daily), are administered. Hydrochlorothiazide ($\frac{1}{4}$ of a 25-mg tablet daily) may be added in refractory cases. When multiple diuretics are administered, close monitoring of serum blood urea nitrogen (BUN) creatinine, and electrolytes is advocated. An ACE inhibitor (enalapril, 0.5 mg/kg daily) is also given. Digoxin ($\frac{1}{4}$ of a 0.125-mg tablet daily or every other day) may be added when the animal appears stable. Because of renal clearance of digoxin, BUN/creatinine should be monitored. Unresponsive CHF may improve with extralabel administration of pimobendan (0.25 mg/kg orally [PO] q12h). Symptomatic ventricular tachycardia is treated with lidocaine HCl (0.25 to 1 mg/kg intravenously [IV] given over 2 minutes or in 1-mg boluses [up to a total of 4 mg for an average-sized cat]). Esmolol (150 to 500 mcg/kg IV bolus or 100 to 300 mcg/kg/min constant-rate infusion) may be added in refractory circumstances with careful blood pressure monitoring. For long-term management of ventricular tachycardia, sotalol (10 to 20 mg q12-24h PO) has been used safely, although efficacy has not been demonstrated. Sequential echocardiograms, thoracic radiographs, and electrocardiograms may assist long-term monitoring.

PROGNOSIS

Generally the treatment of cats with right-sided heart failure has been unrewarding. Heart failure is generally progressive and becomes unresponsive in most cases. Conversely, some affected cats may never become clinically affected. This condition appears to be familial in some breeds. Therefore screening echocardiograms are recommended for siblings of affected animals.

Arterial Thromboembolism in Cats

ANTHONY H. TOBIAS, *St. Paul, Minnesota*

DEBORAH M. FINE, *Columbia, Missouri*

Arterial thromboembolism (ATE) in cats most frequently occurs when a thrombus that develops within the left atrium embolizes a remote site. The most commonly affected site of embolization is the aortic trifurcation, resulting in abrupt occlusion of blood supply to the hind limbs and ischemia of an extremely large muscle mass. Pathologic conditions within the left atrium such as endocardial damage and blood stasis form the substrate for thrombus formation (Smith and Tobias, 2004). In most cases ATE is a devastating complication of serious underlying heart disease.

A recent retrospective study of 127 cats with ATE conducted at the University of Minnesota Veterinary Medical Center (UMVMC) (Smith et al., 2003) demonstrated that ATE is fairly common in referral hospitals, with an incidence rate of 0.57% or 1 in every 175 new feline admissions. Male cats were affected more frequently (67%) than females and were overrepresented when compared to the general feline hospital population (odds ratio = 1.75; $P=0.003$). This likely reflects the higher incidence of hypertrophic cardiomyopathy among males. Middle-aged cats were affected most commonly, but the age range was wide (8.6 ± 4.2 years). Most cases of ATE (81%) occurred in mixed-breed cats, although some purebreds (i.e., Abyssinian, Birman, and Ragdoll) were overrepresented.

A remarkable and striking feature of ATE is the occult nature of predisposing or underlying disease in the great majority of cases. Some cats have a history of cardiac or other predisposing diseases, but ATE was the first indication of any abnormality in 97 (76%) of the 127 cats studied. The only fairly common prodromal feature reported in 16% of cases was vomiting, which occurred minutes to hours before the onset of acute limb signs.

DIAGNOSIS

The diagnosis of ATE is seldom challenging. Most affected cats present because of acute-onset limb lameness, weakness, or paralysis. Affected limbs are virtually always painful (often severely), especially when manipulated, although occasional cats may not manifest overt pain possibly because of a combination of shock and stoicism. Long-standing ischemia eventually reduces pain as a result of peripheral ischemic neuropathy. Musculature frequently is firm, and pulses in the affected limbs are weak or nonpalpable. Nail beds and pads may appear pale to cyanotic. Evaluation of arterial blood flow to the affected limb by

Doppler is a useful adjunct to physical examination. Absence of arterial blood flow lends strong support to a diagnosis of ATE.

The distribution of sites affected by ATE in cats from the aforementioned (UMVMC) study population is presented in Fig. 180-1. Signalment, clinical and vital signs, and results of initial diagnostic procedures are provided in Table 180-1. Important features include the following:

1. In most cats with ATE (72% in the UMVMC study), both hind limbs are affected.
2. Some residual motor function is present in approximately one third of cases, usually among cats in which either a forelimb or single hind limb is affected.
3. Rectal hypothermia is common in cats with both forelimb and hind limb signs, reflecting the profound shock that frequently accompanies ATE.
4. Respiratory rate is markedly elevated in the great majority of cats with ATE, and some show panting or open-mouth breathing. Further, respiratory rate and pattern alone do not provide sufficient clinical information to discriminate between cats with and without concurrent congestive heart failure (CHF). Other diagnostic procedures, especially thoracic radiographs, are required to make this important distinction. Among the UMVMC study cats tachypnea was present in more than 90% of cases, but radiologic or postmortem examination evidence of CHF was present in only 44%. In many cats increased respiratory rate and abnormal breathing patterns are ascribable to pain and metabolic disorders such as acid-base disturbances.
5. Heart murmurs, gallops, and arrhythmias were detected in 57% of the cats in the UMVMC study population, emphasizing the frequently occult nature of underlying disease.
6. Serum concentrations of glucose, alanine transaminase, aspartate aminotransferase, and creatine phosphokinase are frequently elevated, occurring in more than 70% of the UMVMC study cats in which these variables were measured. Other serum biochemistry and electrolyte abnormalities are common but less consistent.

Antemortem diagnostic procedures that included echocardiography or postmortem examinations were performed in 105 of the 127 UMVMC study cats. Underlying disorders among these cats mainly demonstrated

Fig. 180-1 Body areas affected by arterial thromboembolism in 127 cats. The nonlimb sites were cerebral and renal. (Modified from Smith SA et al: *J Vet Intern Med* 17:73, 2003.)

underlying heart disease as presented in Fig. 180-2. Primary or secondary cardiac disorders were identified in 94 (89%) of the 105 cases. Clearly a thorough cardiac evaluation that includes echocardiography should form part of the evaluation for any cat with ATE. Hypertrophic and unclassified cardiomyopathies were the most common diagnoses, but all forms of cardiomyopathy were represented.

Seven cats had a prior diagnosis of hyperthyroidism but were euthyroid with therapy at the time of their ATE episode. It remains to be established whether hyperthyroidism per se is a risk factor for ATE or whether cardiac pathology caused by hyperthyroidism predisposes cats to ATE. The UMVMC data do not provide a definite answer to this question, but most of the study cats with current or treated hyperthyroidism had evidence of cardiac abnormalities at the time of their ATE episode. In our opinion hyperthyroidism is likely to predispose cats to ATE by causing cardiac disease.

Table 180-1

Signalment, Clinical and Vital Signs, and Results of Initial Diagnostic Procedures From 127 Cats With Arterial Thromboembolism

	Reference Range	Data*	n†	%‡ Cases Increased	%‡ Cases Decreased
Signalment					
Gender (male: female)		85:42 (67%:33%)	127

Fig. 180-2 Underlying disorders in 105 cats with arterial thromboembolism in which antemortem diagnostic procedures that included echocardiography or postmortem examinations were performed. (Modified from Smith SA et al: *J Vet Intern Med* 17:73, 2003.)

Neoplasia was second to cardiac disease as the underlying disorder in cats with ATE, occurring in 6% of the UMVMC study cases. No antemortem or postmortem evidence of cardiac disease was present in these six cats. Pulmonary carcinoma is one of the more common tumors associated with ATE, and neoplastic cells may be found within the emboli, suggesting that these may be tumor emboli that originate from the lungs rather than thromboemboli that originate in the left heart (Ibarrola et al., 2004; Smith et al., 2003). In the UMVMC study population tumor types other than pulmonary carcinoma (including hepatocellular carcinoma, vaccine-associated sarcoma, and squamous cell carcinoma) were also associated with ATE. The pathophysiology by which these tumors predispose cats to ATE remains to be established but probably involves paraneoplastic hypercoagulability.

Underlying disorders other than primary or secondary heart disease and neoplasia are uncommon among cats with ATE. Occasionally no cause for ATE is found, and no underlying diseases were identified in 3% of the 105 UMVMC study cases.

PROGNOSIS

Optimal treatment for cats with ATE has yet to be established. Many owners elect euthanasia when confronted with the reality that their cat with ATE has a life-threatening complication superimposed on serious underlying disease. In the UMVMC study population, euthanasia was elected in 25% of cases soon after ATE, and the underlying disease in some cases was diagnosed. Data from this study provide additional prognostic information that should allow both owners and clinicians to make more informed decisions.

A total of 87 of the 127 UMVMC study cats with acute-onset ATE (having occurred within 2 days of presentation) leading to limb signs were treated. Treatments were provided according to the preferences of the attending clinicians. Thrombolysis with streptokinase was attempted in four cases. The remaining cats received unfractionated heparin, aspirin, or both, using a variety

of dosage regimens. Various analgesics were administered (butorphanol, oxymorphone, fentanyl dermal patches, and morphine); and supportive care was provided, as well as treatment for CHF when appropriate. The results of this retrospective study provide the following clinically relevant data:

1. Among the 87 cats with acute ATE in which treatment was provided, 39 (45%) survived to discharge, reflecting the poor prognosis that accompanies this condition. These data are similar to previous retrospective reports.
2. Among the cats that survived to discharge, the period of hospitalization was fairly short (median = 2 days; range = 0 to 10 days). The clinical status of cats with ATE often improves or deteriorates rapidly.
3. Table 180-2 lists the variables that on initial evaluation were significantly different between cats that survived to discharge and those that did not survive. These data show:
 - a. In survivors frequently only one limb was affected, and they demonstrated some motor function.
 - b. Rectal temperature and heart rate both were higher among survivors.
 - c. Serum phosphorous was lower among survivors.
4. Variables that on initial evaluation were not significantly different between survivors to discharge and nonsurvivors were: gender; age; respiratory rate; left atrial dimension; presence or absence of CHF; and serum concentrations of albumin, glucose, blood urea nitrogen, creatinine, sodium, potassium, calcium, alanine aminotransferase, aspartate aminotransferase, and creatine phosphokinase.
5. A logistic regression model for predicting survival to discharge was developed using the variables that were significantly different between survivors and nonsurvivors. Once rectal temperature at presentation was included in the model, accuracy of prediction was not significantly improved by adding any other variables. The model is presented in Fig. 180-3, and it predicts a 50% probability of survival in cases with a

Table 180-2

Clinical And Biochemical Variables From Cats With Acute Thromboembolism That Were Significantly Different Between Survivors to Discharge and Nonsurvivors

	Survivors* (n = 39)	n [†]	Nonsurvivors* (n = 48)	n [†]	P value
Clinical and Vital Signs

Fig. 180-3 Logistic regression model predicting survival probability to discharge (P) based on rectal temperature (T) at presentation. The equation for the model is: $P = 1 / (1 + e^{-47.59 + 0.48T})$. (Modified from Smith SA et al: *J Vet Intern Med* 17:73, 2003.)

rectal temperature of 98.9° F. The predictive value of rectal temperature probably stems from the fact that it reflects overall hemodynamic status and that cats with profound hypotension are often hypothermic and bradycardiac.

A predictive model based on a simple and rapidly measured physical examination variable such as rectal temperature is extremely useful. However, it is also important to recognize its limitations and to interpret the results with care. First, although the model correctly classified 67% of survivors and 79% of nonsurvivors in our study, some cats with ATE are incorrectly classified. Second, the predictive model is based on cats that received a variety of anticoagulant protocols. It remains to be determined how (and whether) more standardized anticoagulant protocols can affect survival to discharge. These approaches are described in the following paragraphs.

Forty-four study cats were discharged from the UMVMC following their acute ATE episodes. This number includes the 39 cases discussed previously, as well as five cats that survived to discharge after referral for further management following ATE of greater than 2 days' duration. Eighteen cats (41%) were discharged on high-dose aspirin (≥ 40 mg total dose/cat orally [PO] q72h), 24 (55%) received low-dose aspirin (5 mg total dose PO q72h), and 2 (4%) received no anticoagulant therapy. Treatment for CHF was prescribed when appropriate (34% of the 44 survivors).

Follow-up of these study cats demonstrated:

1. Eleven of the 44 cats (25%) experienced a total of 16 additional ATE episodes. The episodes were fatal in nine (20.5%) of the cases (three died, six were euthanized). Based on these data, recurrent ATE should be anticipated in about 25% of the cases when aspirin is used for long-term thromboprophylaxis.
2. Among the cats that had additional ATE episodes, average time to first recurrence was 191 ± 152 days (approximately 6 months), but the range was extremely wide.
3. Permanent limb damage is the exception rather than the rule, although time to complete recovery of limb function may be days, weeks, or even months. Complications ascribable to limb ischemia occurred in five (11%) of the 44 discharged cats and ranged from minor tissue necrosis requiring wound management (n=2) to limb contracture (n=1) and limb necrosis requiring amputation (n=2). These results are compatible with previously published reports and textbook descriptions.
4. Nine (20.5%) of the 44 discharged cats were alive at the end of the study period, 9 (20.5%) died or were euthanized because of recurrent ATE, and 26 (59%) died or were euthanized because of progression of their underlying cardiac disease. Recurrent ATE in cats following an acute episode is a significant cause of morbidity and mortality. However, progression of underlying cardiac disease is the single most important cause of morbidity and mortality among cats that

Fig. 180-4 Kaplan-Meier curves for cats that survived to discharge following acute arterial thromboembolism. (Modified from Smith SA et al: *J Vet Intern Med* 17:73, 2003.)

recover from an acute episode of ATE. Mortality from progressive heart disease was almost three times more common than mortality from recurrent ATE.

- Kaplan-Meier curves for cats that were discharged following an acute ATE episode are presented in Fig. 180-4. The curves are plotted by the presence or absence of CHF at the time of their initial episode. Survival time for cats diagnosed with CHF (n=15) was significantly shorter than for cats without CHF (n=29) (median survival times = 77 versus 223 days, $P=0.016$). Thus, although the presence or absence of CHF does not affect survival to discharge among cats with acute ATE, it does have a statistically significant and clinically important effect on mortality following discharge.
- No significant difference in survival was detected between cats that received high- or low-dose aspirin (median survival times = 149 and 105 days, respectively; $P=0.882$), although the numbers treated were relatively low. Further, the proportion of cats that experienced ATE recurrences was similar in the two groups (28% and 25%, respectively). However, 22% of the cats in the high-dose aspirin group showed gastrointestinal side effects versus 4% in the low-dose aspirin group. Thus in this retrospective study efficacy of the two aspirin dosage regimens was not statistically different in terms of survival and ATE recurrence, but adverse gastrointestinal effects were less common among cats receiving low-dose aspirin. Consequently low-dose aspirin is our current recommendation for long-term thromboprophylaxis in cats.

THERAPY

The therapeutic approach that we describe here for the short- and long-term management of cats with ATE involves unfractionated heparin, low-dose aspirin, analgesia, supportive care, and treatment for CHF when appropriate. This therapy is both conventional and conservative. However, we are

frequently disappointed and frustrated by the indifferent results obtained in some cats treated in this manner. Given the magnitude of the perturbation to the system caused by acute ATE, the massive amount of tissue damage, and the seriousness of the underlying disorders in most cases, such responses are not surprising. Nevertheless, many of us continue to search for other therapeutic approaches for both the management of cats with acute ATE and long-term thromboprophylaxis. Some of the alternate strategies that have been proposed and attempted for the management of acute ATE include thrombolytic agents such as tissue type plasminogen activator and streptokinase and surgical and catheter-based removal of thromboemboli from obstructed sites. Currently available information indicates that these strategies are: (1) associated with outcomes that are either worse or no better than those obtained with a more conventional and conservative approach, and (2) based on studies of very few cases with little outcome- or evidence-based comparative data.

Initial management of ATE should include pain control. Butorphanol is too weak and short-acting for this purpose, and for the first 24 to 48 hours opioids are recommended (see Chapter 2). Fentanyl (1 to 3 mcg/kg/hr), hydromorphone, or morphine generally reduces the magnitude of pain. Rectal temperature should be monitored. CHF should be documented by radiography since pain and opioids can affect ventilatory pattern. Furosemide (2 mg/kg intravenously [IV]) and oxygen are appropriate treatments for CHF (also see Chapter 178).

In addition to analgesia, other supportive measures, and treatment for CHF when appropriate, our current anticoagulant recommendations for cats with ATE are:

- Unfractionated heparin 250 to 300 units/kg subcutaneously every 8 hours, with the first dose administered intravenously for cases in shock.*
- Low-dose aspirin (5 mg total dose/cat PO q72h) initiated as soon as the patient is eating.†
- Discontinue heparin gradually over 2 to 3 days once the patient is hemodynamically stable and receiving low-dose aspirin.‡

*In humans a plasma heparin concentration of 0.35 to 0.70 units/ml measured by the chromogenic factor Xa assay is associated with the greatest clinical efficacy and fewest hemorrhagic complications. In normal cats an unfractionated heparin dose of 300 units/kg subcutaneously every 8 hours most consistently provides this concentration. The chromogenic factor Xa assay is the test of choice for heparin monitoring and dose titration, but the assay is not widely available at present. We do not recommend titrating the heparin dose based on activated partial thromboplastin time or activated clotting time. In cats both of these variables correspond very poorly with plasma heparin concentrations measured by the chromogenic factor Xa assay (Smith and Tobias, 2004).

†The rationale for the use of aspirin in general and the low dose of 5 mg/cat orally every 72 hours in particular is provided in Smith and colleagues, 2003.

‡This recommendation is based on the fact that abrupt cessation of heparin in humans may lead to thrombotic complications.

PREVENTION

A variety of drugs for long-term thromboprophylaxis in cats have been investigated either as an alternative or adjunct to aspirin. These include warfarin, low-molecular weight heparin (dalteparin, enoxaparin), ticlopidine, clopidogrel, eptifibatide, and abciximab. Some of these drugs show potential for thromboprophylaxis in cats, and research is ongoing (Smith and Tobias, 2004). In a recent clinical study involving cats with cardiomyopathy, the low-molecular weight heparin dalteparin at a median dose of 99 units/kg subcutaneously every 12 or 24 hours was administered easily by owners and was well tolerated by cats with few side effects (Smith et al., 2004). In another recent study involving five experimental cats, clopidogrel (Plavix), Bristol-Myers Squibb/Sanofi Pharmaceuticals, at total doses ranging from 18.75 to 75 mg/cat q24h PO demonstrated significant antiplatelet activity (Hogan et al., 2004). Many cardiologists empirically use clopidogrel (typically at 18.5 mg PO q24h) as antithrombotic therapy in cats. Currently a multicenter trial of clopidogrel is ongoing. However, it remains to be established whether these drugs can reduce the frequency and severity of ATE in predisposed cats.⁴

We do not recommend warfarin long-term thromboprophylaxis in cats that survive acute ATE episodes. In a study reported by Moore and colleagues (2000) median survival of warfarin-treated cats was only 51 days. Further, the frequency of fatal hemorrhage among the warfarin-treated cats was 17%. Warfarin provides no demonstrable survival benefit over aspirin, is associated with a higher risk of fatal hemorrhage, and requires frequent monitoring of coagulation variables.

A significant subset of cats that survive the acute episode have recurrent ATE, as confirmed by UMVMC study data. Long-term thromboprophylaxis is appropriate for such cases. However, the situation among cats with disorders such as primary or secondary heart disease with or without CHF and no prior history of ATE is more controversial. We are not aware of any studies that have established the frequency of ATE among such cases. Historically large atrial size and the presence of spontaneous contrast or "smoke" on echocardiography have been considered risk factors

for ATE. We subscribe to these notions but recognize that they are based on clinical impression, anecdote, and extrapolation from human medicine. We usually recommend long-term thromboprophylaxis in cats with more severe cardiac disease, prominent atrial enlargement, and spontaneous contrast on echocardiography. Currently low-dose aspirin (5 mg total dose PO q72h) is our drug of choice for long-term thromboprophylaxis in these situations, as it is for cats that survive an acute ATE episode. Low-dose aspirin must be compounded, but it is otherwise easy to administer and requires no specific monitoring. Further, the available data, albeit limited, indicate that the use of low-dose aspirin in cats is associated with minimal adverse effects. Other clinicians use clopidogrel, combinations of low-dose aspirin and clopidogrel, or low-molecular weight heparin as described previously. All of these treatments are empiric at this point, and there have been no blinded, prospective studies comparing treatments or therapy to placebo. It is incumbent on us to search for and embrace new therapies for long-term thromboprophylaxis as soon as their safety and superior efficacy have been established in clinical trials. However, to date no drug or drug combination has been shown to be safer or more effective than low-dose aspirin for long-term thromboprophylaxis in cats that are predisposed to ATE.

⁴This statement is true for aspirin as well. There have been no clinical studies to show that aspirin reduces the frequency or severity of ATE or that it provides a significant morbidity and mortality benefit over no therapy in cats at risk for ATE.

Pericardial Effusion

O. LYNNE NELSON, *Pullman, Washington*

WENDY A. WARE, *Ames, Iowa*

The double-layered pericardial sac surrounding the heart normally contains a small volume (≈ 0.25 ml/kg) of serous fluid between its outer fibrous layer (parietal pericardium) and inner serous membrane (visceral pericardium or epicardium). Excessive fluid accumulation (pericardial effusion) is the most common pericardial disorder in small animals. This occurs much more frequently in dogs than in cats.

PATHOPHYSIOLOGY

Pericardial effusion disturbs cardiac function by impeding filling. Because the pericardium is relatively noncompliant, increases in pericardial fluid volume can sharply increase intrapericardial pressure. When intrapericardial pressure equals or exceeds normal cardiac filling pressure and impairs filling, the condition of cardiac tamponade exists. The fluid accumulation rate and the distensibility of the pericardial sac determine whether and how quickly cardiac tamponade develops. Rapid accumulation of a small volume (e.g., 50 to 100 ml) can raise intrapericardial pressure markedly because the pericardium can stretch only slowly. Fibrosis and pericardial thickening further limit the compliance of this tissue. Pericardial fibrosis and inflammatory cell infiltrates are seen with idiopathic and neoplastic causes of effusion. Conversely, if effusion accumulates slowly, the pericardium may enlarge sufficiently to accommodate the increased volume at low pressure. As long as intrapericardial pressure is lower than venous pressures, cardiac filling and output remain relatively normal, and signs of tamponade are absent. Therefore large-volume pericardial effusion implies a gradual process.

The external cardiac compression that occurs with tamponade progressively limits filling, initially of the right heart but subsequently the left as well. Systemic venous pressure increases while cardiac output falls. Diastolic pressures in all cardiac chambers and great veins eventually equilibrate. Neurohumoral compensatory mechanisms of heart failure become activated as cardiac output falls. External signs of systemic venous congestion and right-sided congestive heart failure become especially prominent with time.

Cardiac tamponade exaggerates the variation in arterial blood pressure that occurs normally during the respiratory cycle. The inspiratory reduction in left heart output can cause a 10-mm Hg or greater fall in arterial pressure during inspiration; this is known as *pulsus paradoxus*. Although myocardial contractility is not affected directly by pericardial effusion, reduced coronary perfusion during tamponade can lead to systolic and diastolic

impairment. Low cardiac output, arterial hypotension, right-sided congestive heart failure, and poor perfusion of other organs, as well as the heart, can ultimately lead to cardiogenic shock and death.

PRESENTATION

Cardiac tamponade is relatively common in dogs but rare in cats. Clinical signs reflect the consequences of systemic venous congestion and poor cardiac output. Right-sided congestive signs usually predominate, especially abdominal enlargement (ascites). Tachypnea and weakness or syncope with exertion is common in the history. Lethargy, poor exercise tolerance, inappetence, cough, and other nonspecific signs can occur before obvious ascites develops. Loss of lean body mass (cachexia) is apparent in some chronic cases. Rapid pericardial fluid accumulation can cause acute tamponade, shock, and death. In such cases pulmonary edema, jugular venous distention, and hypotension may be evident without signs of pleural effusion, ascites, or radiographic cardiomegaly.

Physical examination findings typically include jugular vein distention and/or positive hepatojugular reflux, hepatomegaly, ascites, labored respiration, and weakened femoral pulses. Femoral pulse attenuation during inspiration may be discernible in occasional patients with pulsus paradoxus because of the phasic reductions in pulse (as well as mean arterial) pressure. High sympathetic tone associated with reduced cardiac output causes sinus tachycardia, mucous membrane pallor, and prolonged capillary refill time. The precordial impulse is palpably weak when pericardial fluid volume is large. Subcutaneous edema occasionally is evident. Heart sounds are muffled by moderate-to-large pericardial effusions. Lung sounds are muffled ventrally with pleural effusion. Although pericardial effusion does not cause a murmur, concurrent cardiac disease may do so. Large-volume pericardial effusions sometimes cause clinical signs by virtue of their size, even in the absence of overt tamponade. Lung or airway compression can provoke dyspnea or cough; esophageal compression can cause dysphagia or regurgitation. Fever may accompany infectious pericarditis, and affected patients may appear very ill.

ETIOLOGY

Most pericardial effusions in dogs are serosanguineous or sanguineous and are either neoplastic or idiopathic ("benign") in origin. Transudates, modified transudates, and exudates are found occasionally in both dogs and cats. Pericardial effusions secondary to feline infectious

peritonitis and congestive heart failure (especially hypertrophic cardiomyopathy) are identified most often in cats. Pericardial effusion from lymphoma, systemic infections, and rarely renal failure also are reported in cats. Cardiac tumors are relatively infrequent in dogs; they are rare in cats. Peritoneopericardial diaphragmatic hernia or (rarely) other congenital pericardial malformations may be associated with effusion in both species.

Hemorrhagic effusions tend to be dark red, with a packed cell volume greater than 7%, specific gravity greater than 1.015, and protein greater than 3g/dl. Besides red blood cells, reactive mesothelial, neoplastic, or other cells may be seen on cytology. The fluid does not clot unless hemorrhage was very recent. Neoplastic hemorrhagic effusions are more common in older dogs, although middle-aged and even younger dogs are sometimes affected. Hemangiosarcoma (HSA) is by far the most common cause, followed by heart base tumors and pericardial mesothelioma. HSA usually arises within the right heart, especially the right auricular appendage. HSA appears to have an increased prevalence in certain breeds such as the German shepherd, golden retriever, Afghan hound, English setter, American cocker spaniel, Doberman pinscher, Labrador retriever, and miniature poodle.

Chemodectoma or aortic body tumor (arising from chemoreceptor cells at the base of the aorta) is the most common heart base tumor. Breed predilections include boxers, Boston terriers, and bulldogs; but not all dogs with chemodectomas are of brachycephalic breeds. Other heart base tumors include thyroid, parathyroid, lymphoid, or connective tissue neoplasms. Pericardial mesothelioma is confirmed occasionally in the dog and cat. Pericardial effusion secondary to metastatic tumors appears to be rare. Neoplastic pericardial effusion in cats is most often associated with lymphoma; various other cardiac tumors are rarely involved.

Idiopathic pericardial effusion is most common in medium-to-large dog breeds. Although dogs of any age can be affected, the median age appears to be about 6 to 7 years. Mild inflammation with areas of hemorrhage and diffuse pericardial fibrosis have been described histologically. Less common causes of intrapericardial hemorrhage include left atrial rupture from severe chronic mitral regurgitation, coagulopathy, and penetrating trauma.

Transudative effusions are usually modified rather than pure transudates. Transudative effusions can occur with congestive heart failure, peritoneopericardial diaphragmatic hernia, hypoalbuminemia, pericardial cysts, or toxemias that increase vascular permeability (including uremia). Usually these conditions are associated with a small volume of pericardial effusion, and cardiac tamponade rarely develops. Effusions caused by cardiac lymphoma and rarely by heart base masses can appear transudative rather than hemorrhagic.

Exudative pericardial effusions are rare in small animals. Exudates appear cloudy to opaque or serofibrinous to serosanguineous. They are characterized by high nucleated cell count (well over 3000 cells/ μ l), protein concentration (usually much higher than 3g/dl), and specific gravity (>1.015). Cytologic findings are related to the etiology. Infectious causes usually stem from plant awn migration, bite wounds, or extension of infection in

nearby structures. Various aerobic and anaerobic bacteria, actinomycosis, coccidioidomycosis, disseminated tuberculosis, and rarely systemic protozoal infections have been identified. Sterile exudative effusions have occurred with leptospirosis, canine distemper, uremia, and idiopathic pericardial effusion in dogs and with feline infectious peritonitis and toxoplasmosis in cats.

DIAGNOSTIC EVALUATION OF PERICARDIAL EFFUSION

Blood Pressure

Arterial blood pressure should be measured in all cases of suspected pericardial disease. Hypotension (arterial blood pressure <90) is generally an indication of critical tamponade. Doppler flow detectors may document respiratory variation in audible signal strength compatible with pulsus paradoxus.

Radiography

Thoracic radiography classically reveals a very round cardiac silhouette with large-volume pericardial effusion. The globoid cardiac shadow is especially apparent on the ventrodorsal or dorsoventral projection. However, smaller volumes of pericardial fluid often result in mild-to-moderate generalized cardiomegaly with normal chamber contours, making radiographic diagnosis of pericardial effusion less certain. Sometimes pleural effusion is present. Other radiographic findings commonly associated with pericardial effusion and tamponade include caudal vena cava distention, hepatomegaly, and ascites. Pulmonary vascular underperfusion and interstitial pulmonary edema may be noted. A soft-tissue mass effect may be evident in cases of heart base tumor. The trachea may be deviated or appear displaced dorsally and to the right, distinctly separate from the heart base. Thoracic radiographs are also helpful to screen for other potentially associated lesions such as metastatic lung disease and lymphadenopathy.

Electrocardiography

Electrocardiography is fairly insensitive for detecting pericardial effusion; in many cases the electrocardiogram (ECG) appears normal. However, ECG findings that can suggest pericardial effusion include diminished complex size (<1 mV in all leads), electrical alternans, and ST segment elevation (epicardial injury). Electrical alternans or altering QRS complex height results from physical swinging of the heart within the pericardium. It is best appreciated in large-volume pericardial effusion with the ECG obtained from a standing position. Sinus tachycardia is the most common cardiac rhythm associated with pericardial effusion, but atrial or ventricular tachyarrhythmias may also be noted. Atrial fibrillation can complicate chronic pericardial disease in large-breed dogs.

Echocardiography

Echocardiography is a very sensitive test to detect even small volumes of pericardial effusion. In most cases the

Fig. 181-1 Echocardiogram from a dog with a very tiny amount of pericardial fluid. In this case the fluid is best noted along the caudal left atrial wall at the atrioventricular junction (arrow).

pericardial fluid is hypoechoic; thus pericardial effusion appears as an echo-free space between the epicardium and the intensely hyperechoic parietal pericardium. Because the pericardium is more tightly adhered to the heart base and fluid initially collects ventrally, the apical and caudal left atrial regions are good places to screen for small amounts of pericardial effusion (Fig. 181-1). Occasionally pleural effusion, a markedly enlarged left atrium, or a persistent left cranial vena cava can be confused with pericardial effusion. A thorough scan from numerous positions differentiates these conditions. Particularly when scanning from the right parasternal window, the right ventricular free wall commonly appears hyperechoic because of the dramatic difference in density between the pericardial effusion and epicardium. This should not be interpreted as a right ventricular abnormality or thickened epicardium.

Echocardiography is especially useful in determining the severity of tamponade, which correlates to clinical severity. Tamponade is seen as diastolic collapse of the right atrium and sometimes the right ventricle and is a direct reflection of intrapericardial pressures (Fig. 181-2, A and B). Echocardiography can establish an etiology of pericardial effusion if cardiac or heart base masses are identified and can screen for concurrent disease such as valvular disease, cardiomyopathy, or congenital abnormalities. Whenever possible it is best to perform echocardiographic evaluation before the removal of pericardial fluid. The presence of fluid generally improves visualization of the heart base and location or point of adherence of any mass lesions. Thorough examination of the right atrium and auricle (especially from the left cranial long axis position), ascending aorta, and parietal pericardium are important to screen for neoplasia. In some cases the localization of a lesion may narrow the list of differentials for the effusion (e.g., masses of the right atrium or auricular appendage are consistent with a diagnosis of HSA). Transesophageal echocardiography can be especially useful in examination of the heart base regions for suspected mass lesions and enlarged lymph nodes. Positive and negative predictive values of echocardiography for recognizing cardiac mass lesions have not been reported.

Pericardiocentesis

Pericardiocentesis is the treatment of choice for initial stabilization of animals with pericardial effusion and cardiac tamponade. Pericardial fluid analysis is also a part of the diagnostic process. Aspiration of even a small amount of fluid can markedly reduce intrapericardial pressure and improve clinical status. Diuretic therapy without pericardiocentesis is usually not helpful for cardiac tamponade (except for effusion caused by congestive heart failure). Diuretics can worsen hypotension or precipitate cardiogenic shock.

Fig. 181-2 **A**, Echocardiogram from right parasternal short-axis view of the heart base in a dog with pericardial effusion (end-systolic frame). **B**, The same view in diastole revealing tamponade, with collapse of the right ventricular wall (arrow). Ao, Aorta; P Eff, pericardial effusion; RA, right atrium; RVOT, right ventricular outflow tract.

Fig. 181-3 Common apparatus for pericardiocentesis procedure; a 16-gauge, 6-inch over-the-needle catheter connected to extension tubing and a three-way stopcock.

Pericardiocentesis is performed most routinely from the right side because the cardiac notch reduces the potential for lung injury and the major coronary vessels are located on the left. On a standard examination table the animal is more securely restrained in sternal or left lateral recumbency. A radiographic wedge can be used to elevate the spine slightly. Some clinicians do perform pericardiocentesis in the standing dog. If an echocardiography table or other elevated table with an appropriately sized cutout is available, the animal can be placed in right lateral recumbency and tapped from underneath. Sedation is seldom required for dogs. Echo-guidance may be used but is not often necessary. The ECG should be carefully monitored during the procedure. Needle/catheter contact with the epicardium often induces ventricular arrhythmias (usually with an upright configuration in lead II) and should prompt retraction of the device.

An over-the-needle type catheter is used most commonly for pericardiocentesis (Fig. 181-3). Depending on the size of the animal, a 12- to 20-gauge, 2- to 6-inch-long catheter is selected. Extra side holes may be cut near the catheter tip to facilitate drainage of large-volume or flocculent fluid. Extension tubing is attached to the needle stylet, and a three-way stopcock is placed between the tubing and collection syringe (see Fig. 181-3). Box 181-1 summarizes the pericardiocentesis procedure.

Pericardial Fluid Analysis

Pericardial fluid is submitted routinely for cytology and culture. If obvious masses are not identified by echocar-

Box 181-1

Step-by-Step Approach to Pericardiocentesis

1. Shave the hair over the right precordium (third to seventh rib spaces, sternum to costochondral junction). Prepare the area with aseptic surgical scrub technique.
2. Attach ECG monitor and noninvasive blood pressure if available.
3. Identify the catheter insertion site by palpating the strongest precordial impulse and considering radiographic evaluation and echo-guidance.
4. Local anesthesia should be used, especially with large catheters.
 - a. Infiltrate lidocaine (2%) from the insertion site into the underlying intercostal muscles and pleura.
 - b. Make a small stab incision in the skin (No. 11 blade) if using a large catheter.
5. Insert the catheter with care to avoid the intercostal vessels just caudal to the ribs.
6. Once the needle penetrates the skin and after every increment of advancement, apply gentle negative pressure to the syringe and observe for fluid.
 - a. Pleural fluid is typically straw colored.
 - b. Pericardial fluid is typically dark and bloody; typically this fluid is under a positive pressure.
7. Subtle scratching of the needle tip on the pericardial surface may be noted, or a loss of resistance may be felt as the needle enters the pericardial space. This is not usually associated with ventricular arrhythmias.
8. If the needle contacts the epicardium, marked scratching or pulsing sensation is usually felt. This is usually associated with ventricular arrhythmias. Retract the needle.
9. When a catheter system is used and especially in smaller-volume pericardial effusion, remove the needle and attach extension tubing to the catheter.
10. After a small bit of fluid is obtained, take steps to differentiate the bloody pericardial fluid from hemorrhage.
 - a. Place a drop of fluid onto the table or in a clot tube and observe for clotting (pericardial effusion should not clot).
 - b. Obtain a packed cell volume (PCV) on the fluid and compare it to the peripheral PCV.
11. Aspirate as much fluid as possible from the pericardial space. Submit samples for cytology (and culture if indicated).
12. Verify reduction of effusion and tamponade by echocardiography.

diography, fluid analysis may take on a more important role in determining the next diagnostic and therapeutic steps. Standard laboratory and cytologic evaluation may identify suppurative, mycotic, or chylous effusions but is rarely helpful in distinguishing neoplastic from benign hemorrhagic pericardial effusion. In addition, mesothelial cells lining the pericardium can become reactive and may exfoliate into the effusion. These cells can be difficult to differentiate from neoplastic cells, particularly mesothelioma. Other cardiac-related tumors rarely exfoliate cells into the effusion, with the possible exception of lymphoma.

The therapeutic approach (and prognosis) of animals with pericardial effusion directly depends on the underlying cause of the effusion. Neoplasia and idiopathic pericardial effusion are the most common causes of pericardial

effusion in the dog, but unfortunately fluid cytology does not reliably sort these causes. In addition, certain neoplastic disorders have notoriously short survival times (e.g., HSA). Reports in humans and dogs have examined the use of fluid pH measurement to distinguish between inflammatory and noninflammatory causes of pericardial effusion. Studies in dogs have been conflicting. Theoretically effusions with high pH values are likely from noninflammatory causes (neoplasia), and effusions with low pH values are most likely associated with inflammatory causes (idiopathic or infectious pericarditis). A recent prospective report of 37 dogs with pericardial effusion (Fine, Tobias, and Jacob, 2003) found no correlation between pH and etiology of effusion. Data from this report overlapped 89% of the time between neoplastic and idiopathic effusion groups. At this time there is likely little justification to use pH measurement as a diagnostic test in cases of pericardial effusion.

Advanced Imaging Techniques

The major advantage of computed tomography (CT) and magnetic resonance imaging (MRI) techniques is the ability to noninvasively view internal structures such as the heart. With CT, information is collected from the penetration of x-ray beams projected in a circumferential manner around the chest cavity, and the resulting information is arranged digitally into a two-dimensional image. The images can be reformatted into differing imaging planes corresponding to major anatomic planes (i.e., long axis, short axis planes). On a CT image, black is associated with fluid or air, soft tissues appear as various shades of grey, and bone is white. The relative grayness of the image depends on the relative density of the tissues imaged. Tissue characterization (other than calcium) is limited compared to MRI. Thus the major limitations of CT include the use of ionizing radiation and the frequent need for iodinated contrast to enhance differing tissue densities such as tumors.

Since MRI relies on the magnetic environment of the cellular nuclei, ionizing radiation is avoided. The resulting information is also computer processed to form a two-dimensional image. Cine sequences that loop through the cardiac cycle phases may also be obtained. With advances in software, many pulse sequences can be used for cardiac imaging. They are generally divided into dark (black)-blood and bright (white)-blood techniques. Vessels, cardiac chambers, and soft tissues of varying densities are more easily distinguished; and contrast enhancement is needed less often. In most cases image acquisition must be gated to a point in the cardiac cycle to avoid image blur. MRI may become a valuable tool to detect mass lesions not identified by echocardiography in veterinary patients (Fig. 181-4).

Diagnosis Problems

The most difficult diagnosis involves the mature dog with a hemorrhagic effusion but no overt mass lesion or metastatic disease on cardiac, abdominal, and thoracic imaging. In most cases serial imaging over 2 to 3 months identifies HSA or chemodectoma. Breeds at risk for HSA should undergo careful examination of the spleen and liver.

Fig. 181-4 T1-weighted (black blood) magnetic resonance image of a dog with pericardial effusion. This cystic lesion cranial to the heart (*long arrow*) was not appreciated on transthoracic echocardiography. Histopathologic evaluation revealed the structure to be a rare thyroglossal cyst. An enlarged sternal lymph node is also noted (*short arrow*).

The most common diagnostic challenge is differentiating idiopathic versus mesothelioma-related pericardial effusion. Multiple studies have compared presenting clinical signs and diagnostic and histopathologic findings in cases ultimately diagnosed with pericardial mesothelioma versus idiopathic pericardial effusion. Unfortunately clinical signs and results of noninvasive diagnostic tests are insufficient to differentiate idiopathic effusion from mesothelioma unless a discrete pericardial/intrapericardial mass is observed. Surgical pericardial biopsy can be misleading since both conditions lead to extensive pericardial fibrosis with a mixed inflammatory response incorporating large numbers of reactive mesothelial cells. One retrospective evaluation suggested that recurrence of pleural effusion within 120 days of pericardiectomy increases the likelihood of a diagnosis of mesothelioma (Stepien, Whitley, and Dubielzig, 2000). Survival longer than 120 days after pericardiectomy without chemotherapeutic intervention was unusual in dogs ultimately diagnosed with mesothelioma.

Immunohistochemical staining of biopsy material may be useful to determine etiology of pericardial effusion in questionable cases. Preliminary investigations have evaluated the staining patterns of cardiac HSA, chemodectoma, mesothelioma, and idiopathic pericardial effusion using antibodies specific for CD31, desmin, cytokeratin, vimentin, synaptophysin, chromogranin, and endothelin. In this study the antibody for CD31 was specific for HSA. Synaptophysin and chromogranin demonstrated high specificity but only moderate sensitivity for chemodectoma. Cytokeratin was specific for mesothelial tissue, and desmin occasionally differentiated mesothelioma from reactive mesothelial tissue. If staining characteristics performed on pericardial fluid yield similar results, immunocytochemical stains could potentially improve the diagnostic capability of pericardial fluid analysis. Flow cytometry methods also have shown preliminary value for isolation of neoplastic cells in fluid or blood.

MANAGEMENT OF PERICARDIAL EFFUSION

Initial Management

In most cases systolic function is normal, and positive inotropic drugs are not warranted. Likewise vasodilators and diuretics have a negligible effect on intrapericardial fluid (and pressures) and may only serve to lower systemic arterial pressures. Initial therapy of patients with pericardial effusion is directed at acutely reducing the intrapericardial pressures and enhancing cardiac filling. Thus pericardiocentesis is the treatment of choice and potentially provides some diagnostic information. If a significant volume of fluid is removed, the signs of right heart failure should resolve within days.

After initial pericardiocentesis the next therapeutic step depends on the underlying cause of the effusion. In animals with infectious pericarditis, treatment depends on the organism identified by cytology, culture, or possibly serologic results. Most cases of infectious pericarditis benefit from surgical pericardiectomy; this provides more effective drainage and helps avoid subsequent constrictive pericardial disease. Dogs with idiopathic pericarditis (culture-negative) are often treated conservatively with one or more centesis procedures followed by a course of broad-spectrum antibiotic and antiinflammatory doses of prednisone (1 mg/kg/day) tapering over 2 to 4 weeks. Recovery appears to occur with this approach in about 50% of cases. In cases with recurrent effusion, surgical subtotal pericardiectomy and pericardial biopsy are indicated and associated with very long median survival times. Pericardial removal allows the fluid to drain onto the larger absorptive surface of the pleura.

Neoplastic pericardial effusion with tamponade is also initially treated by pericardiocentesis. Chemotherapy may be palliative in some cases of lymphosarcoma or more rarely HSA and mesothelioma. Periodic pericardiocentesis can be done in some animals with neoplastic disease until the effusion becomes unmanageable. In some cases surgical approaches offer the best management options for neoplastic effusions.

Surgical Management

Pericardiectomy is indicated when multiple pericardiocentesis procedures fail to resolve the effusion, when pericardial constrictive disease is suspected, and when exploration and biopsy are needed to rule out suspected neoplastic or infectious disease. Subtotal pericardiectomy has been done most commonly, with removal of the pericardium below the phrenic nerves; but thoracoscopic partial pericardiectomy has also been described with good results. The pericardium and biopsies of any masses are submitted for histopathologic evaluation. It is unusual to find a discrete mass that can be excised completely since most neoplastic conditions are too extensive at the time of diagnosis.

Animals with idiopathic pericardial effusion typically have a good prognosis after pericardiectomy because the pleural space can readily absorb the relatively small amount of fluid. Animals with neoplastic disease have a

more variable prognosis. Cardiac HSA often has a rapidly progressive course, and metastases are commonly present at the time of diagnosis. Pericardiectomy should be performed cautiously in animals with cardiac HSA because tumor rupture and bleeding into the chest cavity could have dire consequences. Chemotherapy may be palliative in a select group, although there is no compelling evidence that survival times are prolonged significantly. Mean survival times of dogs with cardiac HSA are short, usually 2 to 4 weeks.

Pericardiectomy typically is helpful to alleviate cardiac tamponade in animals with pericardial mesothelioma; however, the procedure is thought to facilitate metastatic dissemination throughout the thoracic cavity. Even so, animals may survive longer with pleural effusion versus pericardial effusion; and in general periodic thoracocentesis is easier to perform. Intracavitary chemotherapy has been attempted in thoracic mesothelioma with limited success. Survival times after identification of pericardial effusion range from 3 to 10 months.

Chemodectoma tends to be slow growing and locally invasive but has a low rate of metastasis. Pericardiectomy in animals with chemodectoma can prolong quality of life for many months to sometimes years and is a good option in many cases.

A newer procedure, percutaneous balloon pericardiectomy, is gaining in popularity in humans for the management of chronic pericardial effusions. This technique also has been shown to be useful in dogs with chemodectoma and idiopathic pericardial effusion. Using general anesthesia and fluoroscopic guidance, a balloon-dilating catheter (14 to 20 mm diameter) may be placed percutaneously (fifth intercostal space) through a catheter-introducer sheath and positioned across the parietal pericardium. Multiple dilations are used to create a small window into the pericardium to allow for drainage. The advantages of this technique include low morbidity and mortality compared to thoracotomy, minimal recovery time, and decreased cost. Disadvantages include the need for special imaging equipment and possible premature closure of the stoma with recurrence of pericardial effusion. An alternative approach is to use a "mini-thoracotomy" and long surgical or laparoscopic instruments to remove a segment of pericardium via the small incisions.

CHAPTER 182

Feline Heartworm Disease

CLARKE E. ATKINS, *Raleigh, North Carolina*

PREVALENCE IN THE UNITED STATES

Heartworm infection is less common in cats than in dogs, approximating 5% to 20% of the canine prevalence in a given geographic area (Ryan, Gross, and Soll, 1996). This has led to a low index of suspicion for feline heartworm disease (FHWD), with resultant underdiagnosis. In addition, the diagnosis of FHWD is often obscured because (1) cats are frequently amicrofilaremic; (2) serologic tests (specifically the enzyme-linked immunosorbent assay [ELISA] antigen and antibody tests) have lacked sensitivity or specificity in cats; (3) worm burdens are small; (4) aberrant sites are more common than in dogs; (5) clinical signs are often nonspecific and different from those seen in dogs; and (6) FHWD can easily be mistaken for feline bronchial disease (asthma) and responds to similar therapies. For these reasons, despite recent efforts at defining the scope of this problem in cats, the exact prevalence of FHWD is unknown and likely underestimated.

The greatest numbers of cases of feline heartworm infection (FHWI) have been reported from the southeastern United States, the Eastern Seaboard, the Gulf Coast, and within the Mississippi River valley (Ryan and Newcomb, 1996). Prevalence studies have focused mainly on cats from shelters (Fig. 182-1). Although this population choice has allowed the use of the relatively sensitive and very specific postmortem diagnosis, these studies are not necessarily applicable to pet cats, even in the same geographic region. These studies have revealed a prevalence of FHWI ranging from 0% to 14% (see Fig. 182-1). There are limited data in pet cats, but a joint study performed on such cats presented to the teaching hospitals of North Carolina State University (NCSU) and Texas A&M University for evaluation of cardio-

respiratory signs demonstrated an infection prevalence of 9% and an exposure rate of 26%; the latter figure was based on antibody titers (Atkins et al., 1998). A number of serologic surveys, largely in asymptomatic cats, have demonstrated exposure rates (antibody seropositivity) of 5% to 36%, even in areas not considered heavily heartworm endemic and as high as 44% in symptomatic cats (Robertson-Plough, 1998). The largest survey to date evaluated over 2000 largely asymptomatic cats in areas by and large not thought to be regions of heavy exposure (Miller et al., 1998). The exposure rate was nearly 12% nationwide (Fig. 182-2). In my opinion heartworm infection should be considered a risk for cats in any locale in which dogs are considered at risk.

DIAGNOSIS

The diagnosis of FHWI or FHWD poses a unique and problematic set of issues. First, the clinical signs in cats are often different from those in dogs, and the index of suspicion is still generally low. Furthermore, the diagnosis is often elusive because eosinophilia is transient or absent and most cats are amicrofilaremic. Radiography, although helpful, is neither adequately sensitive nor specific, requires expertise in interpretation, and is excessively expensive as a screening tool. Echocardiography shows promise in terms of specificity but is costly, only moderately sensitive, and requires special equipment and expertise. Currently the most useful tests are the ELISA serologic tests, but these too are imperfect. The antigen test is very specific but is inadequately sensitive, missing over 50% of natural infections (McCall et al., 1995). On the other hand, the laboratory feline antibody test is very sensitive for exposure (and at least partial larval

Fig. 182-1 Necropsy-proven prevalence of heartworm infection in shelter cats. The shaded states are those in which such studies have been completed. One Michigan study, which showed a prevalence of 2%, was an antigen study.

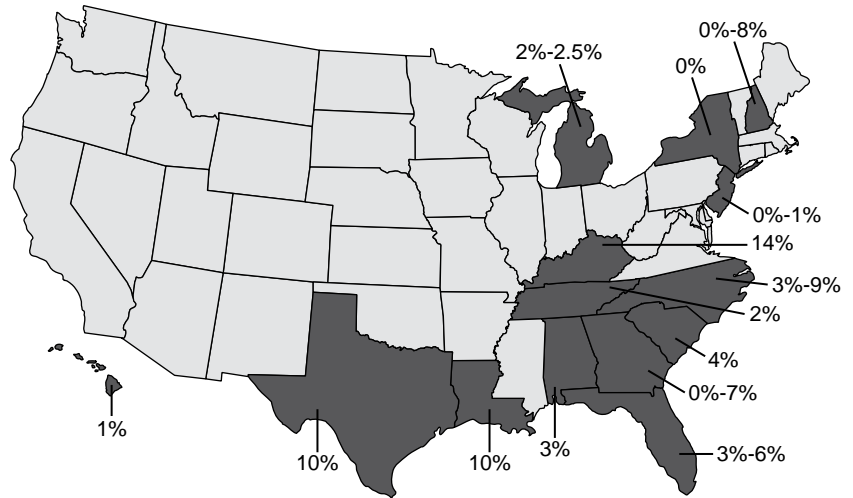

Fig. 182-2 Prevalence (percent antibody-positive) of heartworm exposure in over 2000 largely asymptomatic cats in 19 states (21 regions). NNJ, north New Jersey; CNJ, central New Jersey; LI, Long Island, NY (Miller et al., 2000).

development), but its specificity is low for mature infection, meaning that a positive test indicates exposure but not necessarily adult infection (McCall et al., 1995 and 1998). These two tests are often used in combination or in sequence. If used in sequence, the antibody test is performed first; if positive, the antigen test is then run.

Signalment, History, and Clinical Signs

Although no breeds of cat have been shown to be at increased risk for FHWI, most authors do suspect a male predisposition. This suspicion is based on the overall preponderance of male cats diagnosed with FHWI (71%; Ryan, Gross, and Soll, 1996) and the greater experimental infection rate in males than in females (McTier et al., 1993). However, the experience at NCSU suggests that, although more males (61%) than females are diagnosed with FHWI, the male-to-female ratio is not significantly different from that of the general population of cats seen at a teaching hospital (53% male; Atkins et al., 2000) or the population of cats presented with cardiorespiratory signs (60% male; Atkins et al., 1997). The typical cat with FHWI is 4 to 6 years of age, but the age range varies widely (range <1 to 19 years). The history of outdoor exposure

predicts a heightened risk of heartworm exposure (Miller et al., 1998). Nevertheless, over one fourth of heartworm-infected cats are reported by their owners to be housed totally indoors (Atkins et al., 2000). This may mean that indoor cats can be infected, that owners misinterpret the question when asked, or both. Although a seasonal incidence (August to December) has been suggested for FHWI (Guerrero et al., 1992), other studies do not support this contention (Atkins et al., 2000).

Heartworm-infected cats are often asymptomatic; and clinical manifestations, when present, may take either an acute (often cataclysmic) or a chronic (often waxing and waning) course. Acute or peracute presentation is usually caused by dead worm embolization, anaphylaxis, or migration of worms to the central nervous system. Signs variably include salivation, tachycardia, shock, dyspnea, cough, hemoptysis, vomiting and diarrhea, syncope, dementia, ataxia, circling, head tilt, blindness, seizures, and death. Sudden death, with little or no premonitory signs, has been observed in approximately 10% to 23% of cases (Atkins et al., 2000, Ryan, Gross, and Soll, 1996). Postmortem examination typically reveals pulmonary congestion and edema. Caval syndrome has also been recognized in cats.

Findings in chronic FHWD may include cough, dyspnea, anorexia, weight loss, lethargy, exercise intolerance, vomiting, and signs of right heart failure. Cough is a relatively consistent finding (>50% of cases, compared with 15% in cats with cardiorespiratory signs but not FHWI). When noted in cats in endemic areas, the suspicion of FHWD should increase. Likewise dyspnea, although less specific than cough, is present in 40% to 60% of cases. The pulmonary response to in situ heartworms in cats includes type II cell hyperplasia and activation of pulmonary intravascular macrophages. The latter response, not recognized in dogs, may explain the asthmalike syndrome recognized in some cats, even after they have been cleared of *Dirofilaria immitis* (Dillon, Warner, and Molina, 1996).

Physical examination is often unrewarding, although a murmur, a gallop, and/or diminished or adventitial lung sounds may be noted. In addition, cats may be thin and/or dyspneic. If heart failure is present, elevated heart rate, jugular venous distention, pleural effusion (often chylous), and rarely ascites are detected.

Hematology and Microfilarial Tests and Serology

Hematology

Although the presence of eosinophilia or basophilia may increase the index of suspicion for FHWI, tests for these conditions are of limited value. This is true because these hematologic changes are transient (present at 4 to 7 months after infection) and present in only 33% of cases (Dillon, 1984). In a prospective study of cats with cardiorespiratory signs, those with FHWD were not significantly more apt to have eosinophilia or basophilia than those not shown to be infected (Atkins et al., 1997).

Microfilarial Tests

A definitive diagnosis of FHWI can be made by the detection of circulating microfilariae using the modified Knott test, Millipore filter, direct smear, or microhematocrit techniques. One literature review indicated that 36% of 45 cats with FHWD were microfilaremic (Ryan, Gross, and Soll, 1996), whereas other reports have indicated that no more than 20% of infected cats are microfilaremic (Dillon, 1984; Atkins et al., 1997). This discrepancy probably reflects the fact that at the time of early reports diagnostic methods were limited to microfilarial tests and postmortem examination. Although increasing the volume of blood samples, multiple testing, and drawing evening samples may increase the diagnostic efficiency of the microfilaria-dependent tests, the low percentage of cats that become microfilaremic, the transient nature of microfilaremia, and the low microfilarial numbers seriously limit their usefulness.

Antigen Tests

All heartworm antigen tests currently marketed for dogs can be used in cats. There is now one antigen test kit designed specifically for the cat (SNAP Feline Heartworm Antigen Test, IDEXX Laboratories). Although virtually 100% specific, ELISA antigen tests have been of somewhat limited use in cats because of their inability to detect low worm burdens (one to two or fewer mature female worms); in general, naturally infected cats have

one to three (most often one, almost always less than five) worms. In addition, since current tests detect antigens presumably produced in the reproductive tracts of mature female worms, they do not detect immature (<7 months) or all-male infections. These factors may result in false-negative results, and their importance is underscored by a review of 108 reported naturally occurring cases of feline HWD that revealed that 53% harbored single-worm infections and 18% had all-male infections (Ryan, Gross, and Soll, 1996). Furthermore, it is now clear that pulmonary pathology and presumably clinical signs may exist before worm maturation, at a time when cats are antigen negative (Selcer et al., 1996; Browne et al., 2005). These limitations are demonstrated in two studies. First, in a study of six commercial ELISA antigen tests, positive test results were obtained 36% to 93% of the time from the sera of 31 known positive cats harboring one to seven female worms (McTier et al., 1993). Although sensitivity increased with greater female worm burdens, no all-male heartworm infections were detected. Second, a commercial antigen test allowed detection of fewer than 40% of necropsy-proven, natural infections (McCall et al., 1995). False-negative antigen test results occur frequently, depending on the test used, the maturity and gender of the worms, and the worm burden. Advances in the sensitivity of ELISA antigen tests will probably improve their efficiency in the diagnosis of infections containing at least one female worm. Although the specificity of antigen tests is well accepted, the risk of false-positive results does increase with low prevalence areas. Therefore positive test results should be confirmed by a second test or supported by the presence of appropriate clinical findings (e.g., cough, radiographic lesions, echocardiography).

Antibody Tests

Three “send-off” ELISA antibody tests designed specifically for the diagnosis of FHWI (Animal Diagnostics, Inc., HESKA Corporation, and Antech Diagnostics) and one ELISA antibody test (Solo Step FH, HESKA Corp) designed for in-house use are available commercially. Published data on the “send-off” tests suggests higher specificity than has been found with previous antibody tests (McCall et al., 1998). Although less specific for mature infections than the antigen tests, the commercial ELISA antibody test is capable of detecting male-only and immature infections and has been shown to be useful in the detection of FHWI, even when antigen test results are negative (McCall et al., 1995). The antibody tests were shown to be 100% specific in determining cats to be heartworm negative before infection and detected 80% of experimental infections by 2 months, 97 to 100% by 3 months, and 100% by 4 months after infection (McCall et al., 1998). The antibody test was used to screen 215 random-source cats and detected 7 of 8 necropsy-proven cases (sensitivity = 88%) but at the same time gave false-positive results for 21 cats (90% specificity). The strength of this test is in *ruling out infection* (>99% negative predictive value), but a positive test clearly does not always indicate mature or current infection (positive predictive value <25%). A negative antibody test indicates either no infection or an early (<60- to 90-day) infection. A positive test result is thought to mean that (1) adults are present in the heart and/or

pulmonary arteries, (2) past resolved infection with antibodies is still present, (3) precardiac late larva 4 (L4) or immature L5 infection exists, or (4) ectopic infection is present. Ideally a positive test result should be confirmed with an antigen test, echocardiography, or angiography and supported by the presence of appropriate clinical findings (e.g., cough, radiographic lesions). In addition to aiding in making a diagnosis of FHWD, the antibody test may be useful as a marker for exposure to heartworms, even in cats that never develop mature infection. Finally, the antibody test is currently the most logical single screening test for asymptomatic (and symptomatic) cats.

Imaging: Radiography and Echocardiography

Radiography

Radiographic findings of FHWD (Fig. 182-3) include enlarged caudal pulmonary arteries, often with ill-defined margins; pulmonary parenchymal changes, including focal or diffuse infiltrates (interstitial, bronchointerstitial, or even alveolar); perivascular density; and occasionally atelectasis or pleural effusion. Pulmonary hyperinflation and right heart enlargement may also be evident. Thoracic

radiography has been suggested as an excellent screening test for FHWD. However, although often helpful, thoracic radiography is neither sensitive nor specific in making the diagnosis of FHWD. The single most sensitive radiographic criterion (left caudal pulmonary artery diameter greater than 1.6 times that of the ninth rib at the ninth intercostal space) can be identified in only 53% of cases (Schafer and Berry, 1995) and may also be noted in heartworm-free cats with heart failure. Likewise, pulmonary parenchymal changes are only detectable radiographically in approximately 50% of natural cases (Schafer and Berry, 1995). Even though most cats with clinical signs have some radiographic abnormality, the findings are not specific for FHWD, are variable, and are often transient (Selcer et al., 1996). Finally, radiographic abnormalities have been detected in experimentally exposed cats that ultimately resisted heartworm maturation and were negative on postmortem examination (i.e., false-positive; Selcer et al., 1996). On the other hand, pulmonary angiography can be used to make a definitive diagnosis by the demonstration of radiolucent intravascular "foreign bodies" and enlarged, tortuous, and blunted pulmonary arteries.

Fig. 182-3 **A**, Thoracic radiograph of a cat with mild radiographic signs of heartworm disease. Note the right caudal pulmonary artery (arrow). The arrow is located at the ninth intercostal space, the site for comparison of the ninth rib with the caudal lobar pulmonary artery (either right or left). The finding of a pulmonary artery ≥ 1.6 times the radiographically-measured diameter of the ninth rib is suggestive of heartworm disease in the cat. **B**, Thoracic radiograph obtained from a more severely affected cat. Note the alveolar infiltrate in caudal lung lobes. (From Schafer M, Berry CR: *Vet Radiol Ultrasound* 36:499, 1995, with permission).

Echocardiography

Echocardiography is more sensitive in cats than in dogs for the detection of heartworm infection. Typically a “double-lined echodensity” (Fig. 182-4) is evident in the main pulmonary artery, one of its branches, the right ventricle, or occasionally the heart at the right atrioventricular junction. FHWI was detected echocardiographically in seven of nine natural cases and 12 of 16 experimental infections (Atkins et al., 1997; Selcer et al., 1996). A thorough examination that allows visualization of the bifurcation of the pulmonary artery is essential. A retrospective review of a larger case series (DeFrancesco et al., 1998) revealed a lower sensitivity when worms were not specifically sought and particularly when studies were performed by noncardiologists. This observation underscores the need for a high index of suspicion and expertise if this technique is to be of value in the diagnosis of FHWI. Although echocardiography can be a useful diagnostic tool, it cannot reliably determine worm numbers because of the coiling “posture” of heartworms that produces redundant shadows.

PREVENTION

The question arises as to whether heartworm prophylaxis is warranted for cats because they are not the natural host to *D. immitis* and because the incidence in cats is low. When deciding whether to institute prophylaxis, it is worth considering that the prevalence of FHWI in the southeastern United States and the Mississippi River valley approximates or even exceeds that of feline leukemia virus and feline immunodeficiency virus infections in the United States (Levy, 2006). Furthermore, a 1998 nationwide antibody survey of over 2000 largely asymptomatic cats revealed an exposure prevalence of nearly 12% (see Fig. 182-2; Miller et al., 1998). Finally, the consequences of FHWI are potentially dire, with no clear therapeutic solutions. Therefore I advocate preventive therapy in cats in endemic areas.

Four heartworm preventives with Food and Drug Administration approval are marketed for use in cats in the United States (Table 182-1). Ivermectin (Heartgard, Merial, Ltd.) is provided in a chewable formulation; milbemycin (INTERCEPTOR, Novartis Animal Health) as a flavored tablet; selamectin (Revolution, Pfizer Animal Health), a broad-spectrum parasiticide, comes in a topical formulation; and 10% imidacloprid/1% moxidectin (Advantage Multi, Bayer Animal Health), a broad-spectrum parasiticide is supplied in a topical formulation. It is important to emphasize that four feline heartworm preventives are available, all highly effective with monthly

Fig. 182-4 A two-dimensional echocardiogram obtained from a cat with heartworm disease. A double-lined density (adult heartworm, indicated by arrow) is evident and is diagnostic for heartworm infection. Ao, Aorta; RV, right ventricle; LA, left atrium.

administration and with varied spectra and methods of administration to meet the needs of most clients.

Because cats are rarely microfilaremic, when present, microfilariae occur in low numbers; and, because rapid microfilarial elimination is not seen with most monthly preventives, screening for FHWI before initiation of a preventive is not absolutely necessary. Even though there is no reason to expect adverse reactions to prophylaxis in cats with existing FHWI, it may still be useful to know the heartworm status of cats before institution of a preventive as a gauge of heartworm risk (both for the individual and for other animals in the practice area). The current ELISA antigen tests are not adequately sensitive for this purpose and are not recommended unless the client is properly educated about the limitations of the test. The ELISA antibody test (alone or with an antigen test) is currently more appropriate because of its higher sensitivity and ability to identify cats at risk (infected or exposed).

Based on the severity of FHWI, the lack of an effective and safe adulticidal therapy, and the difficulty in making a definitive diagnosis, I believe that cat owners in endemic areas should be offered heartworm preventive for their feline pets. In addition, cats already infected with heartworms and their housemates should be placed on a preventive.

Table 182-1

Comparisons of Macrolides Currently in Use in Cats for Heartworm Prevention

Drug	HW	Hook	Whip	Round	Tape	Flea/Eggs	Tick	Sarcoptes	Ear Mites
Ivermectin	+	+							
Milbemycin	+	+		+					
Selamectin	+	+		+		+/+			+
Imidacloprid/ moxidectin	+	+		+		+/-			+

THERAPY

Since the vast majority of cats are amicrofilaremic, microfilaricidal therapy is unnecessary in this species. The use of arsencial-adulticides is problematic. Thiacetarsemide is no longer available, and the data on melarsomine in experimental (transplanted) FHWD are limited and contradictory. Although there is an abstract report in which one injection (2.5 mg/kg; one half the recommended canine dose) of melarsomine was administered to experimentally infected cats without treatment-related mortality, the worm burdens after treatment were not significantly different from those found in untreated control cats (Goodman et al., 1996). Diarrhea and heart murmurs were noted frequently in treated cats. A second abstract report, using either the standard canine protocol (2.5 mg/kg twice over 24 hours) or the "split-dosage" (one injection followed by two injections 24 hours apart in 1 month), gave more favorable results (McLeroy et al., 1998). The standard treatment and split-dosage regimens resulted in 79% and 86% reduction in worm burdens, respectively, and there were no adverse reactions. Although promising, these unpublished data need to be interpreted with caution since the transplanted worms were young (<8 months old) and more susceptible and the control cats experienced a 53% worm mortality (average worm burden was reduced by 53% simply by the act of transplantation). In addition, the clinical experience in naturally infected cats has been generally unfavorable, with an unacceptable mortality. Because of the inherent risk, lack of clear benefit, and short life expectancy of heartworms in this species, I do not advocate adulticidal therapy in cats. Surgical or catheter-based removal of heartworms has been successful and is attractive because it minimizes the risk of thromboemboli. Unfortunately the mortality seen in the only published case series was unacceptable (two of five cats; Venco et al., 1999). However, this procedure may hold promise for the future using a less traumatic loop snare, thereby presumably reducing anaphylaxis resulting from worm trauma.

Cats with HWI should be placed on a monthly preventive, and short-term corticosteroid therapy (prednisone, 1 to 2 mg/kg q48h TID) used to manage respiratory signs. If signs recur, alternate-day steroid therapy (at the lowest dosage that controls signs) can be continued indefinitely. For embolic/anaphylactic emergencies, oxygen, corticosteroids (dexamethasone, 1 mg/kg intravenously [IV] or intramuscularly [IM]; or prednisolone sodium succinate, 50 to 100 mg IV/cat), and bronchodilators (aminophylline at 6.6 mg/kg IM q12h; theophylline, sustained release 5 to 7 mg/kg orally [PO] BID; or terbutaline, 0.01 mg/kg subcutaneously [SC]) may be used. Bronchodilators based on the ability of agents such as the xanthines (aminophylline and theophylline), to improve function of fatigued respiratory muscles. In addition, the finding of hyperinflation of lung fields may indicate bronchoconstriction, a condition for which bronchodilation would be indicated. Nevertheless I do not use bronchodilators routinely in FHWD.

The use of aspirin has been questioned because vascular changes associated with FHWD consume platelets, increasing their turnover rate and effectually diminishing the

antithrombotic effects of the drug. Conventional doses of aspirin did not prevent angiographically detected vascular lesions (Rawlings, 1990). Dosages of aspirin necessary to produce even limited histologic benefit approached the toxic range. Despite this, because therapeutic options are limited, aspirin at conventional doses (80 mg PO q72h) is well tolerated, generally harmless, inexpensive, and convenient; and, because the quoted studies were based on relatively insensitive estimates of platelet function and pulmonary arterial disease (thereby possibly missing subtle benefits), I continue to advocate aspirin for *asymptomatic* cats with HWI. Aspirin is *not* prescribed concurrently with corticosteroid therapy. Management of other signs of HWD in cats is largely symptomatic.

PROGNOSIS

In the aforementioned study of 50 cats with natural heartworm infection, at least 12 cats died of causes other than heartworm disease. Seven of these and two living cats were considered to have survived heartworm disease (lived ≥ 1000 days; Atkins et al., 2000). The median survival for all heartworm-infected cats living beyond the day of diagnosis was 1460 days (4 years; range 2 to 4015 days), whereas the median survival of all cats ($n=48$ with adequate follow-up) was 540 days (1.5 years; range 0 to 4015 days). Survival of 11 cats treated with sodium thiacetarsemide (mean 1669 days) was not significantly different from that of the 30 managed without adulticide (mean 1107 days). Likewise youth (≤ 3 years of age), presence of dyspnea, cough, ELISA-positivity for heartworm antigen, presence of echocardiographically identifiable worms, or gender of the cat did not appear to affect survival. Comparison of other cardiovascular disease prognoses to FHWD reveals that survival is roughly equivalent to that of hypertrophic cardiomyopathy (Atkins et al., 2003).

CHAPTER 183

Canine Heartworm Disease

MATTHEW W. MILLER, *College Station, Texas*
 SONYA G. GORDON, *College Station, Texas*

Despite the availability of several very effective and safe preventive medications, heartworm disease continues to be an important disease of both dogs and cats. This chapter briefly reviews the life cycle of this parasite, diagnostic studies, and staging of disease. Treatment and prevention of canine dirofilariasis is the focus of this chapter. Feline heartworm disease is described in the preceding chapter.

DIAGNOSIS AND STAGING OF CANINE HEARTWORM DISEASE

Life cycle of *Dirofilaria immitis*

A basic knowledge of the life cycle of the heartworm parasite is important for understanding strategies for prevention, diagnosis, and therapy. The mosquito is a requisite intermediate host for transmission of this disease. The

first-stage larvae (L_1) or microfilaria are ingested by the mosquito following a blood meal from an infected animal. The parasite molts twice within the mosquito, and these molts are required for the parasite to develop into the infective third stage (L_3). The parasite maturation within the mosquito from L_1 to L_3 requires approximately 2 to 3 weeks. In addition, appropriate environmental conditions are necessary for development. One of the most important of these is an average daily temperature in excess of 64° F for longer than 30 consecutive days.

The L_3 larvae are the infective stage of the parasite and are transmitted to a susceptible host following a bite from an infected mosquito. The third larval stage travels within the subcutaneous tissues of the new host, molting to the fourth larval stage (L_4) in approximately 1 to 2 weeks and becomes a young adult (L_5) in 30 to 60 days. These young adults enter the systemic venous system and are carried to the lungs approximately 100 days after infection. Under

ideal conditions the infection can become patent (adult worms producing microfilaria) in 5 months, but more often this complete cycle requires in excess of 6 months.

Establishing a Diagnosis

The American Heartworm Society (AHWS) (www.heartwormsociety.org) recommends that an adult heartworm antigen (Ag) be used as the primary screening test for the disease in dogs. There are numerous suppliers of the heartworm Ag test, and readers are referred to excellent comparative articles (Atkins, 2003; Courtney, 2001) for relative sensitivity and specificity of these tests. Ag testing is substantially more sensitive than microfilarial concentration tests. In addition, the widespread use of monthly preventive medication has decreased the sensitivity of the microfilarial tests by rendering the vast majority of infections amicrofilaremic (occult) while having no effect on the sensitivity of the Ag tests. Circulating Ag is generally undetectable until 6 to 7 months following infection.

As a general rule, weakly positive test results should be rechecked by either repeating the original test or submitting a sample for evaluation using a different Ag test, preferably at a reference laboratory. False-positives occur infrequently but are almost always associated with technical errors. False-negative tests are usually the result of immature infections, infection with low female worm numbers, or all male infections. Another potential but less likely cause for a false-negative test is complexing of circulating Ag with antibody, leaving insufficient free Ag available for detection.

The use of concentration tests for detection of circulating microfilaria is no longer recommended for routine screening of patients with suspected infection. The simultaneous use of both an Ag and a concentration test has been advocated by some since it may increase the likelihood of establishing a definitive diagnosis on the small percentage of cases in which a very low number of gravid females is present or on the patient in which all Ag is complexed. However, once a positive Ag test is obtained, performing a concentration test to determine the concentration of circulating microfilaria is important. This information may

dictate the preventive medication used. Some preventive medications (milbemycin) are potent microfilaricides at the suggested preventive dose and may be associated with substantial risk of a shocklike reaction when administered to heavily microfilaremic dogs. It is prudent to recommend that the client observe a microfilaremic patient for the entire day following administration of the first dose of preventive, no matter what preventive is used.

Classification and Staging

Before heartworm therapy the dog with heartworm infection should be classified, optimally based on radiographic findings and laboratory studies. When heartworm disease causes clinical signs, these are generally attributable to pulmonary parenchymal injury, pulmonary arterial injury, or cardiac dysfunction. Additional infrequently encountered clinical syndromes include severe glomerular disease, caval syndrome, and disseminated intravascular coagulopathy.

There are a number of ways to classify patients with positive heartworm tests. One approach is related to the use of the Immiticide brand of melarsomine and is based on the Food and Drug Administration (FDA)-approved label (Table 183-1). The drug package insert for Immiticide provides very detailed and specific information about this classification system. Another way is to consider heartworm patients in terms of clinical syndromes or presentations, an approach that overlaps the aforementioned classification system but also provides additional perspective regarding treatment approaches. Dogs can be characterized clinically as follows:

- *Asymptomatic* or equivocal signs: Heartworm infection is evident, but there is no clear evidence of disease.
- *Respiratory signs* of heartworm disease, including cough and tachypnea with exercise: These problems are often related to heartworm-induced pneumonitis or lung fibrosis; some but not all dogs also have evidence of pulmonary vascular disease.
- *Cor pulmonale*—Radiographic evidence of significant pulmonary vascular disease: Typical clinical findings include limited exercise capacity and possibly

Table 183-1

Classification of Heartworm Disease Severity in Dogs

Class	Clinical Signs	Radiographic Signs	Clinicopathologic Abnormalities
1: Mild	None or occasional cough; fatigue with exercise or mild loss of condition	None	None
2: Moderate	None or occasional cough; fatigue with exercise; mild or moderate loss of condition	Right ventricular enlargement and/or some pulmonary enlargement \pm perivascular and mixed alveolar-interstitial opacities	\pm Mild anemia (PVC 20%-30%); \pm proteinuria
3: Severe	General loss of condition or cachexia; fatigue on exercise or mild activity; occasional or persistent cough \pm dyspnea or right sided heart failure	Right ventricular \pm right atrial enlargement; moderate-to-severe pulmonary artery enlargement; perivascular and mixed alveolar-interstitial opacities	\pm Anemia (PVC <30%); \pm proteinuria
4: Very severe	Caval syndrome		

PVC, Premature ventricular contraction.

exertional collapse or syncope; some but not all dogs have significant pulmonary parenchymal changes.

- *Congestive heart failure* (CHF): Right-sided heart failure is a complication of severe pulmonary vascular disease and pulmonary hypertension and cor pulmonale that follow.
- *Caval syndrome*—an acute syndrome related to a large worm burden, severe pulmonary hypertension, and right ventricular dysfunction with tricuspid regurgitation: Hepatic congestion and intravascular hemolysis with hemoglobinuria are classic clinical signs
- Heartworm infection or disease in a dog with *serious comorbid conditions*: Examples include malignant neoplasia, diabetes mellitus, and chronic renal failure.

ADULTICIDE THERAPY FOR CANINE HEARTWORM DISEASE

If necessary, dogs with heartworm disease should be classified and stabilized before adulticidal therapy. Dogs with *significant respiratory signs* and pulmonary infiltration generally are treated with glucocorticoids, typically prednisone at 0.5mg/kg once or twice daily for 7 to 14 days. Patients with eosinophilic pneumonitis often show a marked improvement in clinical signs. Dogs with *severe cor pulmonale* based on radiographic signs (or evidence of heart failure) should be given strict rest before and after adulticidal treatment. Other therapies, including aspirin and heparin, have been used empirically in dogs with severe cor pulmonale, but there is no consensus for their use, and we do not recommend these drugs. There is a clear risk of gastrointestinal bleeding with aspirin therapy, and the risk is extremely high if nonsteroidal antiinflammatory drugs are combined with corticosteroids. When *right-sided CHF* is evident, adulticide therapy is delayed for a number of weeks until CHF has been stabilized and resolved medically (see Chapter 171). In general, the management of CHF in heartworm disease involves strict rest, furosemide to effect, an angiotensin-converting enzyme inhibitor, and possibly pimobendan. Dogs with caval syndrome should be referred immediately to a hospital experienced in removing filarial parasites. Melarsomine should not be given to dogs with caval syndrome. Patients with heartworm infection suffering from other serious systemic disorders are generally handled on a case-by-case basis.

Melarsomine Dihydrochloride (Immiticide)

The only currently approved drug for adulticide therapy is melarsomine dihydrochloride (Immiticide) (Merial). It is safer and more efficacious than its predecessor (sodium caparsolate). Most often the drug is administered at 2.5 mg/kg intramuscularly twice, 24 hours apart. In more severe cases, especially in dogs with marked cor pulmonale (heartworm class 3; see Table 183-1), melarsomine should be administered in a “split dose,” which consists of an initial injection followed in approximately 1 month by a series of two injections over a 24-hour period. This lowers the initial kill rate, thereby diminishing the impact of dying worms on the pulmonary vasculature.

Despite the enhanced safety of this product, adverse reactions are still noted. In fact, by definition successful pharmacologic adulticidal therapy dictates thromboembolic events. The severity of this complication can be diminished by restricting exercise after melarsomine administration and by using the split-dose regimen recommended for class 3 heartworm disease. A 4- to 6-week period of severe exercise restriction after adulticidal therapy is recommended. The method and degree of exercise restriction varies with the client needs and the pet's inherent activity level but might include hospitalization, cage rest, sedation, housing in a restricted room of the house or garage, and only gentle leash walks.

Nevertheless, some owners do not or cannot restrict exercise, resulting in or worsening thromboembolic complications. In addition, severe adverse reactions may be noted when dogs are incorrectly (or even correctly) categorized as class 1 or class 2 heartworm disease severity and subsequently treated with the traditional two-injection regimen. To minimize the chance of thromboembolic complication it would be reasonable to adapt an alternative approach, using the three-injection (split-dose) method in all class 1, 2, or 3 heartworm infections.

Split versus Standard Dosing of Melarsomine

Studies have shown that patients treated with the split-dose regimen (three total doses) have a higher seroconversion to a negative Ag status (89.7%) rate than patients treated with either caparsolate (65.9%) or the standard melarsomine dosing regimen of a total of two doses 24 hours apart (76.2%). In addition, in a study using experimental heartworm infection in dogs, more effective adulticide activity did not appear to increase the severity of clinically apparent pulmonary hypertension or thromboembolism. Perhaps more important, killing worms in two increments of approximately 50% each diminishes the insult to the lung and pulmonary vasculature. This approach is critical in dogs with advanced cor pulmonale. After approximately 50% of the worms are destroyed, there is a 1-month interval for the lungs to heal before the second insult of dying worms starts. Furthermore, if there is a significant adverse reaction to the initial adulticidal injection, the second and third injections can be delayed (or even cancelled) until clinical signs have resolved and damaged tissue can heal (i.e., typically in 2 to 3 months).

Disadvantages to this split or two-step approach include the added cost of the third injection. This may be counteracted by reduction in adverse reactions, which often require hospitalization and intensive therapy. Second, the total arsenic dosage is increased, which may be an issue in the dog with significant renal disease. Despite these concerns, we have found the approach to be well tolerated generally, and we advocate a two-dose regimen with supportive fluid therapy for dogs with significant renal disease requiring heartworm adulticidal therapy. Finally, exercise restriction is often a problem for owners, and the “split dose” regimen requires approximately 2 months' exercise restriction (Fig. 183-1). This may prove difficult for some owners.

We believe that the split, three-injection approach of melarsomine administration provides the best management strategy for virtually all heartworm infections.

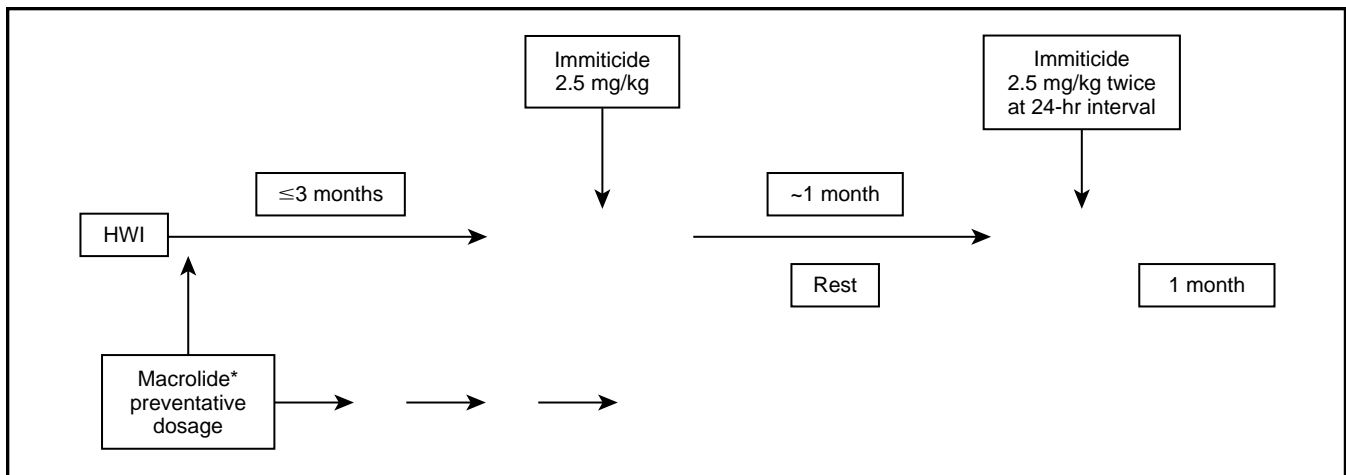

Fig. 183-1 Our preferred approach to adulticidal therapy in all dogs infected with heartworms includes three doses of melarsomine. Macrolide prophylaxis is begun at the time of diagnosis, if not already in use. *If microfilaremic, care should be given to prevent or observe and treat adverse reactions, based on microfilarial numbers and macrolide used. See text for complete description.

This treatment regimen is safer and probably more effective than the two-dose regimen, justifying the increased cost. The AHWS now advocates this approach as well. Even if owners cannot afford the minimum database for evaluation of general health and the presence and severity of heartworm disease, they may still benefit financially by use of the three-dose regimen. In such instances, even though the attending clinician has more difficulty predicting an adverse reaction without thoracic radiographs, the likelihood of adverse reaction (and attendant costs) can be reduced by this approach.

Administration and Clinical Use of Melarsomine

At the time of heartworm diagnosis by a positive Ag test, we recommend completing a database that includes a patient history, complete physical examination, microfilaria test, serum chemistry panel, complete blood count, urinalysis, and thoracic radiographic evaluation. At this time a monthly macrolide preventive is prescribed (see Figure 183-1). This approach is used to prevent further infection; to eliminate microfilariae (since this renders the dog risk free as a reservoir of infection); and to destroy developing L_4 larvae, a stage not susceptible to adulticidal therapy. The risk of an adverse reaction in microfilaria-negative dogs (occult infection) is very low with any preventive. In microfilaremic dogs the first macrolide dosage is administered in the hospital or at home with observation so that an adverse reaction might be recognized and treated promptly. Corticosteroids with or without antihistamines (either dexamethasone at 0.25 mg/kg intravenously [IV] and Benadryl at 2 mg/kg intramuscularly [IM] or 1 mg/kg of prednisolone orally [PO] 1 hour before and possibly 6 hours after administration of the first dose of preventive) are administered in our practice to reduce the potential for adverse reaction in patients with high microfilaria counts. It is important to emphasize that adverse reactions are unusual with macrolides at preventive doses; however, the risk is probably greater with milbemycin than with the doses of ivermectin, selamectin, or moxidectin used for prevention of heartworm infection.

Depending on the time of year, as long as 2 to 3 months might be allowed to lapse before adulticidal therapy is administered. Monthly macrolide administration ensures that the dog is at no risk of additional infection and prevents maturation of infections of 3 months' duration or less. Theoretically infections of 4 months but less than 6 months are too old to be prevented with monthly preventives, but the immaturity of the worms would make them relatively resistant to therapy with melarsomine. Administering preventives for 2 to 3 months before administration of the first dose of melarsomine would not only prevent young infections from maturing, but the delay also would allow larval maturation to adulthood, ensuring that the only stage of the life cycle present is the mature L_5 , which is vulnerable to melarsomine therapy. This delay is particularly important if the diagnosis is made during or at the end of a mosquito exposure season. If the diagnosis is made in the spring or late winter when infective larvae are most likely mature, adulticidal therapy may be initiated immediately (see Fig. 183-1).

The first injection of melarsomine is administered by deep intramuscular injection (2.5 mg/kg) in the lumbar musculature as described fully in the package insert. The injection needle is changed before injection, and care is taken to inject deep into the muscle. The injection site is recorded. It is important to place the injection in the center of the epaxial muscle. Typically patients are hospitalized for the day of the injections. Some dogs seem to experience discomfort, depression, or nausea following injection; for this reason some clinicians administer butorphanol (0.3 to 0.4 mg/kg IM) before injection. Sedation also helps to ensure excellent injection technique. The need for exercise restriction for at least 1 month is emphasized, and sedation is provided if necessary. Owners are also advised regarding potential adverse reactions (fever, lethargy, inappetence, cough, dyspnea, and collapse) and to call if they have concerns. Since these signs are often related to the predictable pulmonary reaction to dead worms, some clinicians routinely dispense prednisolone (0.5 mg/kg daily) to be used specifically for signs

of increased coughing, tachypnea, or lethargy. Generally 5 to 7 days of therapy are sufficient to overcome pulmonary reactions to dead worms. The owners are advised that they must return for a second series of two injections in approximately 1 month.

If serious systemic reaction results, the second stage of the adulticidal treatment may be delayed or even cancelled. However, even with severe postadulticide reactions, the entire treatment protocol generally is completed within 2 to 5 months (see Fig. 183-1). After a minimum of 1 month the melarsomine injection procedure is repeated; the injection site is recorded again. If significant local reaction was noted after the first injection, dexamethasone or oral nonsteroidal antiinflammatory drugs are used to minimize pain at the injection site that accompanies subsequent injections. Butorphanol can also be used as described previously. The following day (approximately 24 hours after the first injection) the process is repeated with injection into the *opposite* lumbar area. Client instructions are similar to those previously given, with reemphasis of the need for strict exercise restriction.

Ag testing is repeated 6 months following the second series of injections; a positive test result indicates incomplete adulticidal efficacy. It is emphasized that, despite the proven efficacy of melarsomine, not all worms are killed in every patient. Typically worm burden is markedly reduced; but if as few as one to three adult female worms remain, positive Ag tests are likely. Whether or not repeat adulticidal therapy is warranted under these circumstances is decided on a case-by-case basis, with input from the owners and perhaps a specialist.

The Role of Wolbachia

Like most filarial nematodes, *D. immitis* harbors obligate, intracellular, gram-negative bacteria belonging to the genus *Wolbachia* (*Rickettsiales*). Studies in non-*D. immitis* filariae demonstrated that treatment with tetracyclines during the first month of infection was lethal to some *Wolbachia*-harboring filariae but not to a filaria that did not harbor *Wolbachia*. In addition, treatment of *Wolbachia*-harboring filariae suppressed microfilaremia. Although similar studies with *D. immitis* have not yet been reported, in one study tetracycline treatment of heartworm-infected dogs resulted in infertility in the female worms. It has been suggested that *Wolbachia* contributes to pulmonary and renal inflammation through its surface protein WSP, independently from its endotoxin component. Studies to determine the role of *Wolbachia* in the pathogenesis of heartworm disease and the clinical use of suppressing these populations with doxycycline before adulticide therapy may provide an additional means by which to reduce the severity of postadulticide therapy. Some clinicians are already suggesting pretreatment of animals with doxycycline for 30 days before adulticide therapy; however, there are no published data to demonstrate better outcomes with this approach.

Monthly Preventives as Adulticides

Much has been written about the adulticidal properties of the monthly preventives. Some individuals have

suggested that the adulticidal properties represent an alternative to melarsamine. The variable efficacy of the preventives is correlated with what is frequently called *reach-back*. This term is misleading in that the property that is being described is simply a reflection of efficacy against older infections. Based on data published thus far, ivermectin has the highest efficacy against mature infections. McCall and colleagues (2001) reported that, when given monthly for longer than 24 months at the standard preventive dose, ivermectin is 98% effective against 5-month-old worms and 95% effective against 7-month-old worms. The same efficacy data have not been published in older infections. Despite these intriguing results Rawlings and colleagues (2001) showed that dogs with 5.5- to 6.5-month-old infections started on the label doses of either ivermectin or milbemycin developed radiographic changes and necropsy findings similar to dogs with the same age infections that were untreated. These results reinforced the recommendations of the AHWS that dogs be tested with an Ag test *before* being started on preventive medication and that *dogs found to be AG positive receive treatment with an adulticide before starting on a preventive medication*.

Elimination of Circulating Microfilaria

Historically, elimination of circulating microfilaria has been attempted several months following adulticide therapy as the second step in the treatment of a patent infection. The general recommendation now is that elimination of circulating microfilaria be accomplished as a secondary benefit of chemoprophylaxis, although some argue that rapid elimination of circulating microfilaria will more quickly eliminate a potential disease reservoir. Despite this concern, the monthly preventives will eliminate microfilaria and also that reservoir of infection.

It is sometimes difficult to eliminate circulating microfilaria before completion of adulticide therapy. However, even without adulticide therapy, circulating microfilaria can be eliminated with several sequential months of therapy with a macrocyclic lactone, including ivermectin, milbemycin oxime, moxidectin, and selamectin. As previously mentioned, administration of a macrocyclic lactone should begin as soon as a definitive diagnosis is established.

The macrocyclic lactones are the safest and most effective microfilaricidal drugs to date. However, none of these drugs is approved currently as a microfilaricide by the United States FDA. Use of the monthly preventives for this purpose is covered by the Animal Medicinal Drug Use Clarification Act of 1994, which allows licensed veterinarians extralabel use of certain drugs that have an established clinical application, provided a valid veterinarian-client-patient relationship exists. Ensuring proper dose administration and providing appropriate aftercare when products are used in an extralabel application are the personal responsibilities of the dispensing veterinarian. The AHWS has taken a firm stance on the use of high-dose ivermectin for rapid elimination of microfilaria. The following is from the current treatment guidelines: "It is both unnecessary and dangerous to use livestock preparations of these drugs (ivermectin) to achieve higher

doses for the purpose of achieving more rapid results." They go on to suggest that, if rapid elimination of circulating microfilaria is deemed important, milbemycin oxime should be used since it is the most potent microfilaricide producing the most rapid rate of microfilaria clearance. Clearance of circulating microfilaria can also be accelerated by administering the monthly preventive dose of any of the currently available macrolides every 2 weeks. Once the microfilaria are cleared, the standard dose should be administered monthly.

Again, the need for rapid clearance of microfilaria is controversial and not without potential complications. Although most reactions are mild and transient (lethargy, inappetence, salivation, and retching), important clinical manifestations of rapid microfilaria death can occur and include hypotension, pale mucous membranes, tachycardia, and collapse. High-risk dogs should be observed for the first 8 to 12 hours following administration of potentially microfilaricidal drugs. We pretreat these dogs with prednisolone, 1 mg/kg orally, or dexamethasone, 0.25 g/kg intravenously, 1 hour before administration of the first dose of monthly preventive to a microfilaria-positive dog. Although severe reactions are seen most commonly in dogs with high microfilaria counts, occasionally dogs with microfilaremia as low as 5000 microfilaria per milliliter develop acute circulatory collapse.

HEARTWORM PREVENTION IN DOGS

Canine heartworm disease is an almost completely preventable disease despite the fact that the dog is an exceptionally susceptible host. Administration of heartworm prophylaxis is suggested for all dogs living in endemic areas. Although year-round chemoprophylaxis may not be necessary throughout the northern half of the country, it is important to remember that successful seasonal prophylaxis depends on proper timing of heartworm *preventive* administration. When heartworm transmission can potentially occur over more than 6 months, seasonal chemoprophylaxis may not be the most effective method of prevention. Year-round treatment should be considered to enhance compliance and control other parasitic infections.

The currently available macrolides (ivermectin, milbemycin, moxidectin, and selamectin) have all been shown to have exceptional efficacy when administered appropriately at recommended doses and dosing intervals. The ideal *preventive* medication is the product that best promotes client compliance.

Product Switching

Occasionally the type of preventive medication used needs to be switched. Rarely does this result from intolerance to the product. More often it is related to perceived superiority or preference of administration route (topical versus oral) by the client, the prescribing veterinarian, or both. When product switching occurs, it is important to establish a temporal line of evidence regarding the Ag status of that animal so that, in the unlikely event of a prevention failure, the circumstances of the break can be ascertained.

Although this may seem superfluous, there have been so-called prevention failures with heartworm preventives, and this approach establishes the most likely cause. We recommend obtaining a contemporary Ag test at the time of product switch. Any infection that is 6 months old or older would be expected to result in an Ag-positive status and therefore implicate the first product as responsible for prevention failure. If the Ag test is negative, the new product is begun at the appropriate dosage, and a retesting schedule established. Any infection that is 3 months old or younger will almost certainly be prevented by monthly administration of all the currently available preventives. Conversely, a 4-month-old infection, although not identified by the initial Ag test, will, depending on the product used, probably go on to become a mature infection. Seroconversion will most likely occur 6 to 7 months after infection or 2 to 4 months after the Ag tests performed at the time of product switching. Any new infection associated with exposure during that time would be too young to be detected by an Ag test. Therefore repeating the Ag test 4 months after the product was switched allows the veterinarian to determine if a prevention break occurred while the patient was receiving the initial product. If the Ag test at 4 months is negative, it is very strong evidence that the initial product was effective. Seroconversion to a positive status 4 months or more after product switching implicates the replacement product as the cause for the prevention break.

Managing the Patient With Polyuria and Polydipsia

KATHARINE F. LUNN, *Fort Collins, Colorado*

Polyuria and polydipsia are common problems in small animal medicine. Although a client may report only polyuria or polydipsia, these two disorders generally are considered as one problem, typically termed *polyuria/polydipsia (PU/PD)*, as neither polyuria nor polydipsia can persist in isolation. The textbook definitions of polyuria and polydipsia include urine output in excess of 50 ml/kg/day and water intake greater than 100 ml/kg/day, respectively. In practice, these definitions are rarely used to determine if a patient exhibits PU/PD. Measurement of water intake can be difficult or inconvenient for many clients, and measurement of urine output is rarely if ever performed in patients in their home environment. Although measurement of these parameters is more feasible in a hospital setting, they may not provide a true reflection of the patient's usual behavior. It should also be recognized that an individual patient can be polyuric and polydipsic without exceeding the limits described here. For example, a 5-kg cat would have to consume more than 500 ml of water per day to meet the classical definition of polydipsia; most cat owners would recognize increased water intake at a considerably lower volume than this. *Therefore it is more clinically useful to place PU/PD on the problem list if the owner has observed that water intake and/or urine output are increased compared to their usual observations and the urine specific gravity (USG) is found to be persistently low.* Measurement of the pet's water intake at home is perhaps most useful in cases in which there is discordance between the owner's observations and the USG. In some patients PU/PD may be placed on the problem list regardless of owner observations if the clinician notes a persistently low USG on urinalysis.

NORMAL PHYSIOLOGY

Water intake and urine production are controlled by the hypothalamus, pituitary gland, and kidney. Thirst is stimulated primarily by small changes in plasma osmolality. Thus a water deficit leads to hyperosmolality, which stimulates osmoreceptors, resulting in thirst. Arterial hypotension, fever, pain, and certain drugs also can stimulate thirst. Antidiuretic hormone (ADH; vasopressin; arginine vasopressin [AVP]) is synthesized in the supraoptic and paraventricular nuclei of the hypothalamus and stored in the pituitary. Release of ADH is stimulated by the same factors that stimulate thirst. ADH secretion can also be

stimulated by nausea, hypoglycemia, stress, pain, fever, exercise, and some drugs. In the healthy kidney fluid leaving the ascending loop of Henle and early distal convoluted tubule is always dilute, regardless of the level of ADH. In the late distal convoluted tubule and the collecting duct, ADH promotes the passive resorption of solute-free water. In the absence of ADH the membranes in this part of the nephron are impermeable to water. ADH exerts its effects by binding to vasopressin (V2) receptors in the distal renal tubule, ultimately leading to the insertion of water channels (aquaporin-2) into the apical membrane of the epithelial cells. These channels allow water to flow along the osmotic gradient between the distal convoluted tubule/collecting duct and the hypertonic renal medulla. The countercurrent multiplier system of the renal tubules establishes hypertonicity in the renal medullary interstitium, and this is maintained by the vasa recta. Slow blood flow in the vasa recta prevents "wash-out" of medullary solutes such as sodium, chloride, and urea.

CAUSES OF POLYURIA AND POLYDIPSIA

PU/PD are the clinical manifestations of failure to produce concentrated urine. As described previously, the physiologic processes that allow for concentration of the urine include the presence of ADH, the ability of the renal tubules to respond to ADH, and the presence of an osmotic gradient between the hypertonic renal medulla and the fluid in the distal convoluted tubule and collecting duct. Thus PU/PD can result from reduced or absent ADH synthesis or release, failure of the renal tubule to respond to ADH, or reduction in the osmotic gradient between the filtrate in the distal convoluted tubule and the renal medullary interstitium. Reduction in the osmotic gradient can be caused by the presence of osmotically active particles in the filtrate or decreased medullary hypertonicity. In all of these situations polyuria is the primary problem, resulting from an inability to produce concentrated urine, and the animal manifests a compensatory polydipsia. In contrast, primary polydipsia is a disorder of thirst and may result from a psychogenic (behavioral) abnormality in which hypothalamic, pituitary, and renal function are normal. Fever, pain, and hyperthyroidism can also cause polydipsia. In addition, polydipsia can be a normal physiologic response to environment changes such as elevated ambient temperature or the feeding of a dry diet.

It is rarely possible to distinguish clinically between primary polydipsia and primary polyuria; although the evaluation of serum sodium concentration $[Na^+]$ or measured osmolality, when available, may be helpful in some cases. Serum $[Na^+]$ at or below the lower limit of the reference range is suggestive of a primary polydipsia. In contrast, high-normal or elevated serum $[Na^+]$ supports the presence of primary polyuria. This distinction is not helpful in all patients with PU/PD since many have a normal serum $[Na^+]$. In addition, low serum $[Na^+]$ may be associated with hypovolemia. It is also important to recognize that some conditions that cause PU/PD may do so by more than one mechanism. For example, patients with hyperadrenocorticism may demonstrate PU/PD because of impaired central release of ADH, reduced renal responsiveness to ADH, or psychogenic polydipsia. Patients with liver failure may manifest both psychogenic polydipsia and decreased renal concentrating ability as a result of decreased blood urea nitrogen (BUN) production and reduced renal medullary hypertonicity.

Primary Polydipsia

Primary polydipsia may be a behavioral problem, sometimes attributed to insufficient exercise or a stressful environment or associated with particular personality types or breeds of dogs. This condition is uncommon in dogs and rare in cats. Primary polydipsia may explain the PU/PD seen in cats with hyperthyroidism, and it has been suggested to accompany primary gastrointestinal disease in dogs. Primary polydipsia can also be a manifestation of hepatic encephalopathy, and it may at least partly explain the PU/PD that accompanies canine hyperadrenocorticism. Patients with primary polydipsia are able to concentrate their urine in response to water deprivation.

Primary Polyuria

Primary polyuria may result from absent or reduced ADH synthesis or release or from failure of the renal tubules to respond to ADH. The former condition is termed *central diabetes insipidus* (CDI). Failure of the renal tubules to respond to ADH is called *nephrogenic diabetes insipidus* (NDI). This may be a primary disorder, or it may be secondary to many other conditions.

Central Diabetes Insipidus

In CDI the deficiency of ADH may be partial or complete and the result of trauma, neoplasia, congenital defects, or idiopathic causes. The diagnosis is made by demonstrating that the patient is unable to produce concentrated urine in response to water deprivation but responds to the administration of exogenous ADH.

Primary Nephrogenic Diabetes Insipidus

This is a rare congenital disorder in which the renal tubules are unable to respond to ADH. Affected animals have an obligate polyuria and do not concentrate their urine in response to water deprivation or administration of exogenous ADH.

Secondary Nephrogenic Diabetes Insipidus

Table 184-1 lists the many causes of secondary NDI. This category encompasses the vast majority of causes of PU/PD in the dog and cat and includes the most common causes of PU/PD, as well as many uncommon disorders. Polyuria is the primary problem in these disorders and is the result of an acquired inability of the renal tubules to respond to ADH. This may be because of a loss of the normal osmotic gradient between the renal medullary interstitium and the fluid in the distal renal tubule, or it may result from interference with the actions of ADH on the renal tubular cells. A water deprivation test is of no value in the investigation of secondary NDI; each disorder must be ruled out by specific diagnostic tests.

Renal Medullary Solute Washout

Fluid therapy, diuretic therapy, and chronic PU/PD may result in the loss of renal medullary solutes, leading to an impaired renal response to ADH. This can interfere with renal concentrating ability in response to water deprivation or a 1-desamino-8-D-AVP (desmopressin) (DDAVP) trial; therefore a gradual period of water restriction to restore a normal concentration gradient may be recommended before these tests are performed.

Miscellaneous Causes of PU/PD

Diet, drugs, and toxins can lead to PU/PD through a variety of mechanisms. Therefore a thorough diet and drug history is an essential part of the evaluation of the patient with PU/PD. Many clinicians have noted that dogs with splenomegaly, splenic masses, or bladder tumors may have a history of PU/PD; however, the mechanism is not known. Similarly dogs with gastrointestinal disease may be polyuric and polydipsic; this is suggested to be a psychogenic problem, perhaps in response to gastrointestinal pain or discomfort.

DIAGNOSTIC APPROACH TO POLYURIA AND POLYDIPSIA

Table 184-1 includes the primary diagnostic tests that are used to investigate specific causes of secondary NDI. The diagnosis of CDI and primary polydipsia is discussed in the Stages of Testing in PU/PD later in the chapter. The following guidelines should be kept in mind when formulating a diagnostic plan for a polyuric and polydipsic dog or cat:

1. Investigate the common disorders first. The most common causes of PU/PD in the dog are chronic renal failure, hyperadrenocorticism, and diabetes mellitus. In the cat the most common causes are chronic renal failure, diabetes mellitus, and hyperthyroidism.
2. CDI is rare, primary NDI is very rare, and primary polydipsia is uncommon. Therefore do not pursue diagnostic tests for these disorders until more common differential diagnoses have been thoroughly ruled out.
3. Always begin the diagnostic plan with tests that are simple to perform and interpret, safe for the patient,

Table 184-1

Causes of Secondary Nephrogenic Diabetes Insipidus, Underlying Mechanisms, and Recommended Diagnostic Tests

Cause	Mechanism(s)	Recommended Diagnostic Tests	Comments
Diabetes mellitus	Osmotic diuresis	Urinalysis Blood glucose Serum fructosamine	
Primary renal glycosuria	Osmotic diuresis	Urinalysis	
Fanconi syndrome and other tubulopathies	Osmotic diuresis	Urinalysis Urine electrolyte and amino acid levels	
Chronic renal failure	Osmotic diuresis	Serum chemistry Urinalysis GFR measurement	Absence of azotemia does not rule out chronic renal failure Patients with mild to moderate renal failure retain urine diluting ability
Polyuric acute renal failure	Osmotic diuresis	Serum chemistry Urinalysis	
Postobstructive diuresis	Osmotic diuresis Down regulation of aquaporin-2	History Physical examination	
Chronic partial ureteral obstruction	Down regulation of aquaporin-2	Abdominal radiography Abdominal ultrasonography Excretory urography	
Renal medullary solute washout	Decreased renal medullary tonicity with loss of osmotic gradient	Find underlying cause	
Pyelonephritis	Bacterial endotoxin reduces tubular sensitivity to ADH Damaged countercurrent mechanism	Urinalysis and urine culture Abdominal ultrasonography Ultrasound-guided pyelocentesis Excretory urography	A single negative urine culture does not rule out pyelonephritis
Pyometra	Bacterial endotoxin reduces tubular sensitivity to ADH	History and physical examination Abdominal imaging	"Stump" pyometra is possible in a spayed female
Liver failure	Loss of medullary hypertonicity Impaired hormone metabolism	Fasting and postprandial bile acids	PU/PD may also have a psychogenic component
Portosystemic shunt	Loss of medullary hypertonicity Increased GFR	Fasting and postprandial bile acids Abdominal ultrasonography Portography Rectal scintigraphy	PU/PD may also have a psychogenic component

Hyperadrenocorticism	Impaired tubule response to ADH	ACTH stimulation test Low-dose dexamethasone suppression test	Impaired release of ADH and psychogenic polydipsia may also contribute to PU/PD in patients with hyperadrenocorticism
Hypoadrenocorticism	Loss of medullary hypertonicity	ACTH stimulation test	
Hyperthyroidism	Loss of medullary hypertonicity	Total T ₄ Free T ₄ by equilibrium dialysis Thyroid scintigraphy	PU/PD may also have a psychogenic component
Acromegaly	Osmotic diuresis due to diabetes mellitus Interference with action of ADH?	History and physical examination GH levels (not readily available) IGF-I levels Brain imaging	Partial CDI may contribute to PU/PD in some patients
Pheochromocytoma	Excessive catecholamines	History and physical examination Abdominal imaging Hormonal assays	Hormonal assays not commonly performed in veterinary medicine
Primary hyperaldosteronism	Impaired tubule response to ADH	Aldosterone levels Renin activity	Impaired release of ADH may also lead to CDI
Hypercalcemia	Interferes with action of ADH on renal tubule	Serum chemistry Ionized calcium	Many possible causes of hypercalcemia
Hypokalemia	Down regulation of aquaporin-2 Loss of medullary hypertonicity	Serum chemistry	
Hyponatremia	Loss of medullary hypertonicity	Serum chemistry	
Leiomyosarcoma	Impaired tubule response to ADH	Abdominal imaging	
Polycythemia	Action of atrial natriuretic peptide	Complete blood count	Impaired release of ADH may also lead to CDI
Leptospirosis	Mechanism(s) unknown	Serology Polymerase chain reaction	Renal failure is not the cause of PU/PD in all cases

ACTH, Adrenocorticotrophic hormone; *ADH*, antidiuretic hormone; *CDI*, central diabetes insipidus; *GFR*, glomerular filtration rate; *GH*, growth hormone; *IGF-I*, insulin-like growth factor I.

and inexpensive for the client. The water deprivation test does not meet these criteria.

4. Take advantage of a written reference list of differential diagnoses for PU/PD so that disorders can be removed from the list as they are ruled out.
5. Do not completely rule out differential diagnoses for PU/PD without definitive evidence. For example, not all dogs with hyperadrenocorticism “look cushingoid,” and not all patients with pyelonephritis have an active urine sediment. Use specific diagnostic tests to investigate these differential diagnoses.

The following sections review a logical, stepwise approach to PU/PD. In some cases diagnostic tests are chosen from more than one stage concurrently, based on the overall clinical picture and the most likely diagnoses.

Stage One Testing in Polyuria and Polydipsia: the “Minimum Database”

A careful history, complete physical examination, urinalysis, complete blood count (CBC), serum chemistry profile, and urine culture are mandatory in the initial evaluation of all patients with PU/PD. Consideration of the species, breed, age, sex, and history of the patient allows the differential diagnoses for PU/PD to be placed in order of likelihood. For example, chronic renal failure, hyperadrenocorticism, and diabetes mellitus are more likely in middle-aged dogs than in puppies. A careful history of the reported PU/PD also helps to rule out other disorders of urination such as pollakiuria or urinary incontinence. As indicated previously, a complete diet and medication history is essential to rule out iatrogenic causes of PU/PD such as glucocorticoid administration or the feeding of a highly protein-restricted diet. The physical examination may be normal in many patients with PU/PD, but it may also reveal signs of disorders such as hyperadrenocorticism or neoplasia. A complete urinalysis, serum chemistry profile, and CBC allow many of the disorders listed in Table 184-1 to be ruled out. Subtle changes in the chemistry profile and CBC may also provide diagnostic clues. For example, minor changes in serum $[\text{Na}^+]$ may help to distinguish between primary polyuria and primary polydipsia. Decreases in cholesterol, albumin, and BUN may suggest liver failure, and thrombocytosis and a stress leukogram may prompt further evaluation for hyperadrenocorticism.

Urine culture should be performed in all patients with PU/PD to investigate pyelonephritis and because many causes of PU/PD predispose the patient to the development of urinary tract infections (e.g., diabetes mellitus, hyperadrenocorticism, and chronic renal failure). Although sediment evaluation is important, it cannot be used to rule out infection because it is difficult to visually detect bacteria in the sediment prepared from a urine sample with a low USG and because several disorders that cause PU/PD also inhibit the development of an active urine sediment. If pyelonephritis is suspected, a single negative urine culture cannot rule this out; additional cultures, as well as further diagnostic tests outlined in Stage Three Testing in PU/PD, should be performed.

Serum total thyroxine (T_4) measurement in cats and leptospirosis titers in dogs are also considered part of the minimum database for PU/PD. Leptospirosis is recognized increasingly as a cause of PU/PD in dogs, and serologic testing is recommended in all geographic locations with the exception of desert environments.

Interpretation of Urine Specific Gravity

The terms *isosthenuria*, *hyposthenuria*, and *hypersthenuria* refer to urine that is isoosmolar, hypoosmolar, or hyperosmolar, respectively, compared to plasma. Thus an accurate assessment of urine concentration requires measurement of urine and plasma osmolality. In practice osmolality is not measured routinely; therefore ranges of USG are used to define isosthenuria (USG of 1.008 to 1.012), hyposthenuria (USG <1.008), and hypersthenuria (USG >1.012). By convention the term *hypersthenuria* is often used to refer to highly concentrated urine (USG >1.035 in the dog; USG >1.045 in the cat); and the term *minimally concentrated urine* describes USG in the range of 1.013 to 1.030 (dog) and 1.013 to 1.040 (cat). Measurement of several random USGs can be useful in the evaluation of the patient with PU/PD. Detection of a random USG greater than 1.030 indicates that the patient does not have an obligate polyuria and suggests that the problem is one of primary polydipsia. In most cases a definitive diagnosis cannot be obtained by evaluation of USG alone; however, certain differential diagnoses can be rendered more or less likely by the evaluation of several USGs. For example, marked hyposthenuria is most likely with CDI or primary polydipsia, and hyposthenuria can occur with many diseases causing secondary NDI (e.g., hypercalcemia, hyperadrenocorticism, and pyelonephritis). Although it is true that patients with chronic renal failure normally produce isosthenuric or minimally concentrated urine, if renal failure is mild to moderate, the patient is still *capable* of diluting the urine if another disorder is present. For example, an animal with both chronic renal failure and psychogenic polydipsia would be able to produce hyposthenuric urine unless the renal failure was advanced. Conversely it is important to note that several renal disorders other than chronic renal failure interfere with concentrating ability. These disorders may lead to production of hyposthenuric urine, and this finding should not lead the clinician to eliminate the possibility of renal *disease* as a cause of PU/PD. Important examples include pyelonephritis and hypercalcemia, which can lead to irreversible renal failure if not suspected, diagnosed, and managed.

Stage Two Testing in PU/PD: Ruling Out Specific Differential Diagnoses

If the minimum database has failed to diagnose the cause of PU/PD, further tests are recommended to continue to rule out the many causes of secondary NDI. Although the index of suspicion may be low for many of these disorders, it is important to rule them out before proceeding to a potentially harmful test such as water deprivation. The adrenocorticotrophic hormone (ACTH) stimulation test is a valuable test in the investigation of PU/PD in the dog. This test is sensitive and specific for

the diagnosis of hypoadrenocorticism, and the results may also identify iatrogenic hyperadrenocorticism. The ACTH stimulation test has a moderate sensitivity for the diagnosis of pituitary-dependent hyperadrenocorticism and lower sensitivity for the diagnosis of adrenal-dependent hyperadrenocorticism; therefore a normal ACTH stimulation test result should prompt follow-up with a low-dose dexamethasone suppression test if there is any clinical suspicion of hyperadrenocorticism. Fasting and postprandial bile acids are recommended in the evaluation of the patient with PU/PD to rule out either acquired liver failure or a congenital portosystemic shunt. Not all patients with these disorders have elevated liver enzymes or decreased liver products (BUN, cholesterol, albumin, and glucose) on a chemistry panel; therefore a more specific and sensitive test of liver function is recommended. Serum T_4 levels should be part of the minimum database in the feline patient with PU/PD. In dogs, although hyperthyroidism is rare, this differential diagnosis is simply ruled out with a serum total T_4 assay. If hyperthyroidism is suspected in a cat but not confirmed by the total T_4 , repeated T_4 measurements, free T_4 by equilibrium dialysis, or thyroid nuclear scintigraphy should be considered.

Stage Three Testing in PU/PD: Imaging Studies

Imaging studies in the patient with PU/PD may be used to screen for a range of disorders that were not detected on initial testing. For example, thoracic and abdominal radiographs may reveal evidence of neoplasia, and abdominal ultrasound may demonstrate splenic or adrenal masses. Imaging studies may also be indicated in the pursuit of specific diagnoses. Examples include abdominal ultrasound to look for “stump” pyometra or partial urinary tract obstruction, excretory urography or ultrasound-guided pyelocentesis to investigate suspected pyelonephritis, and imaging of the brain in suspected acromegaly or CDI.

Stage Four Testing in PU/PD: Uncommon Disorders

Assessment of Glomerular Filtration Rate

Glomerular filtration rate (GFR) studies are indicated in the evaluation of patients with PU/PD that demonstrate persistent unexplained isosthenuria or minimally concentrated urine with normal BUN and creatinine (see Chapter 189). Loss of approximately 66% of functional renal mass results in loss of concentrating ability, but azotemia does not develop until more than 75% of functional renal mass is lost. Therefore normal BUN and creatinine cannot be used to rule out chronic renal failure in a patient that has lost more than 66% but less than 75% of functional renal mass. Commonly used methods of GFR assessment include iothexol clearance, exogenous creatinine clearance, and nuclear scintigraphy. Water deprivation could potentially lead to decompensation in a patient with undetected chronic renal failure; therefore assessment of GFR is recommended before considering this step.

Response to DDAVP

DDAVP, or desmopressin, is a synthetic analog of ADH. Desmopressin is used to treat CDI and is also used in the final stages of a water deprivation test to determine if the patient is able to respond to exogenously administered ADH (as would be expected in CDI but not in NDI). A therapeutic trial with DDAVP has been described (Nichols, 2000); this approach is a recommended alternative to the water deprivation test. Desmopressin is available as tablets (0.1 and 0.2 mg), nasal solution (0.1 mg/ml or 1.5 mg/ml) and parenteral injection (4 mcg/ml). For the DDAVP trial the 0.1-mg/ml nasal solution is preferred and is administered into the conjunctival sac (1 to 4 drops q12h for 5 to 7 days). Before starting the DDAVP trial the patient's water intake is measured over 2 to 3 days to provide a baseline value. A positive response to the DDAVP trial is indicated by a reduction in water intake or an increase in USG. These findings support a diagnosis of CDI but may also be seen in patients with hyperadrenocorticism. A DDAVP trial should only be considered under the following circumstances:

1. Stages 1, 2, and 3 of the diagnostic plan have been completed, and all testable causes of secondary NDI have been ruled out.
2. Patient signalment, history, and serum $[Na^+]$ are more consistent with CDI than primary polydipsia.
3. The patient will be closely observed and given free access to water.

Success of a DDAVP trial depends on appropriate owner compliance and objective monitoring of water intake and USG during the trial. Although rare, hyponatremia or volume overload could result from excess DDAVP activity in an animal without CDI.

Gradual At-Home Water Deprivation

If patient signalment, history, and serum $[Na^+]$ are more consistent with primary polydipsia than CDI, gradual water deprivation may be considered in selected cases. This approach is not recommended unless the following conditions are satisfied:

1. All causes of primary polyuria have been considered and ruled out.
2. The patient has a normal or low-normal serum $[Na^+]$.
3. The patient has a normal BUN and creatinine.
4. The patient is not clinically sick or dehydrated.
5. The client and veterinarian are committed to frequent evaluation of patient body weight and USG, as well as daily measurement of BUN and serum $[Na^+]$.
6. The client is motivated, well informed, observant, and compliant.

Before starting water deprivation, the patient's normal water intake should be established over 3 to 5 days. This amount can then be decreased by no more than 5% per day while normal food intake and activity level are continued. The test is discontinued if the patient loses 5% or more of body weight, serum $[Na^+]$ or BUN become elevated, clinical signs of illness develop, or USG increases to 1.030 or greater. If USG is 1.030 or higher at any point, the diagnosis of primary polydipsia has been confirmed. Again, because of the significant risks associated with

water deprivation in a patient with an obligate polyuria, this test is not recommended unless the conditions listed previously have been satisfied. Animals may be referred for more intensive in-hospital water deprivation assessment in unusual cases.

CHAPTER 185

Interpreting and Managing Crystalluria

JOSEPH W. BARTGES, *Knoxville, Tennessee*
CLAUDIA A. KIRK, *Knoxville, Tennessee*

Crystalluria is defined as the observation of crystals during microscopic examination of a centrifuged urine sample. Occasionally crystalluria may be heavy enough to be observed macroscopically. Crystalluria represents elimination of a solid (minerals and electrolytes) in a liquid medium (urine).

The most common crystals observed in dog and cat urine are struvite (magnesium ammonium phosphate hexahydrate), calcium oxalate dihydrate, ammonium urate, and cystine. In addition, other ions and certain drugs are capable of forming crystals in urine. Amorphous crystals, which lack a classic symmetric structure, are commonly observed in dog urine and sometimes in cat urine. Typically amorphous crystals are variant forms of struvite; however, other ions such as ammonium urate may appear amorphous.

CRYSTAL FORMATION

Crystals form when the urine is or has recently been oversaturated with the ions that make up the crystals. With oversaturation the minerals cannot remain dissociated (dissolved), and they combine to form an organized structure (a crystal). The microscopic appearance of the crystals depends on their composition. The concentrations of minerals, urine volume, urine pH, temperature, and the presence of promoters and absence of inhibitors of crystal formation all influence crystal formation. The

concentration of crystallogenic compounds depends on the ion excretion rate and the volume of urine produced. The less urine excreted, the higher the concentrations of solids in the urine. In addition, urinary pH and the presence of other ions affect the relative concentration and the solubility of certain compounds in urine (Table 185-1); and the presence of cellular debris, foreign bodies, mucosal erosions, or even other crystals can serve as a surface or scaffolding to enhance crystal formation.

Temperature influences crystal formation as well. Temperature variation is not likely in the urinary bladder, but it does influence precipitation of crystals after collection. If the urine is allowed to cool below body temperature, crystals are likely to precipitate. Most crystals form in an acidic urine (pH <7.0), whereas a few (particularly struvite) form when the urine pH is greater than 7.0 (see Table 185-1). The presence of a surface such as denuded mucosa, a piece of suture, or another mineral promotes crystal formation. Finally, certain compounds inhibit crystal and stone formation. For example, Tamm-Horsfall mucoprotein and nephrocalcin are protein inhibitors of crystal formation (Carvalho et al., 2003). Although the role of these proteins in canine and feline crystal formation is not well defined, the inhibitory activity can be influenced by urine pH.

Crystalluria is influenced by both diet and water intake. Dietary influence on crystal formation may

Table 185-1

Common Characteristics of Canine and Feline Urinary Crystals

Type	Appearance	pH WHERE COMMONLY FOUND		
		Acid	Neutral	Alkaline
Ammonium urate	Yellow-brown spherulites, thorn apples	+	+	±
Amorphous urates	Amorphous or spheroid, yellow-brown structures	+	±	–
Ampicillin	Long, thin needles that are colorless	+	?	?
Bilirubin	Reddish-brown needles or granules	+	–	–
Calcium carbonate	Large yellow-brown spheroids with radial striations or small crystals with spheric ovoid or dumbbell shapes	–	±	+
Calcium oxalate dihydrate	Small colorless envelopes (octahedral form)	+	+	±
Calcium oxalate monohydrate	Small spindles, “hemp seeds” or dumbbells	+	+	±
Calcium phosphate	Amorphous, or long, thin prisms	±	+	+
Cholesterol	Flat, colorless plates with corner notch	+	+	–
Cystine	Flat, colorless hexagonal plates	+	+	±
Hippuric acid	4- to 6-sided colorless elongated plates or prisms	+	+	±
Leucine	Yellow-brown spheroids with radial and concentric laminations	+	+	–
Sodium urate	Colorless or yellow-brown needles or slender prisms, sometimes in clusters or sheaves	+	±	–
Struvite	3- to 6-sided colorless prisms	–	±	+
Sulfa metabolites	Sheaves of needles with central or eccentric binding; shucks of wheat comprised of slender sheaves that grow in such a way as to form two half circles with central budding; sometimes fan-shaped clusters; sometimes globules with striations	+	±	–
Tyrosine	Fine, colorless or yellow needles arranged in sheaves or rosettes	+	–	–
Uric acid	Diamond or rhombic rosettes, or oval plates, structures with pointed ends. Occasionally six-sided plates	+	–	–
Xanthine	Amorphous, spheroid, or ovoid structures with a yellow-brown color	+	±	–

±, Crystals may occur at this pH but are more common at the other pH.

include (1) altered excretion of dietary constituents or metabolites; (2) dietary-induced alteration of urinary pH; or (3) changes in urine volume. Alterations in urinary pH, ion excretion, and urine concentration can be observed following the initial consumption of a new food and may not reflect a pathologic process (e.g., a hospitalized patient consuming a novel diet). However, in most cases of dietary change, urine composition stabilizes in 4 to 7 days. Time of feeding with respect to urine collection and feeding method can have a significant influence on the urine pH and possibly crystalluria. A postprandial alkaline tide (urine alkalinization) is common 3 to 6 hours after eating, particularly in meal-fed animals. Some pharmacologic agents result in crystalluria. Identification of unusual crystals in urine should prompt review of medications that the animal may be receiving. Drugs associated with crystalluria include sulfadiazine and its metabolites, ampicillin, and radiopaque contrast agents (see Table 185-1) (Osborne et al., 1999). In humans ciprofloxacin, primidone, 5-fluorocytosine, 6-mercaptopurine, and acyclovir also have been associated with crystalluria.

Occasionally foreign material may be mistaken for crystalluria, depending on method of urine collection. Pollen and other environmental contaminants (e.g., clay litter) may be collected with voided urine samples. Talc powder

crystals from surgical gloves may be introduced into urine samples during collection of a midstream voided sample or during insertion of a urinary catheter.

SIGNIFICANCE OF CRYSTALLURIA

Crystalluria is not synonymous with urolithiasis. Crystalluria occurs when urine is or has recently been oversaturated with crystallogenic compounds; however, crystalluria by itself is not pathologic. For example, many adult dogs have struvite crystalluria; however, struvite uroliths do not form in adult dogs unless there is a urinary tract infection with a urease-producing microbial organism (typically *Staphylococcus* spp. or *Proteus* spp.). Therefore struvite crystalluria in adult dogs is rarely a concern unless an infection is present. Likewise, many animals with cystinuria have crystalluria, but the incidence of cystine urolith formation is low (Tsan et al., 1972). Urolith formation in immature Dalmatians occurs uncommonly despite the presence of urinary urate crystals; and in immature Dalmatians urate crystalluria is not predictive of future urolith formation in adulthood (Bartges et al., 1999a). Nonetheless, crystalluria does represent a potential risk factor for urolith formation.

In contrast to the observation that crystalluria does not predict urolithiasis, uroliths can occur without observable crystalluria. Patients may have active urolith disease but not have crystalluria. Two potential explanations for this phenomenon are (1) oversaturation is intermittent, and the urine sample was collected during a period of relatively low saturation; or (2) precipitating crystals are rapidly incorporated into a preexisting urolith (Bartges et al., 1999b). In practice most dogs and cats with struvite and ammonium urate uroliths do have crystalluria; however, more than 50% of dogs and cats with active calcium oxalate uroliths do not have crystalluria (Lulich et al., 1999).

Interpretation of crystalluria depends highly on how the sample was collected and how it was analyzed. Most important, crystals may form in urine after it is collected (in vitro crystallization). Crystals may not be present in urine while at body temperature in the urinary bladder; however, if it is cooled after collection (e.g., by refrigerating the sample), crystals may form. Crystals may also form if the urine sample undergoes evaporation. To correctly assess crystalluria, a urine sample should be collected fresh and examined within 15 to 20 minutes (unrefrigerated) and immediately if refrigeration of the sample is anticipated. It may be beneficial to keep the urine at body temperature. Refrigerated samples should be allowed to return to room temperature before urinalysis and urine sediment examination are completed.

Crystal aggregates occur when crystals stick together in clumps. This implies a propensity for the microscopic crystals to adhere together and organize over time, which is a prerequisite for macroscopic urolith formation. However, presence of crystal aggregates must be interpreted in light of how the sample was collected and processed and taking into account factors such as animal species and gender (Osborne et al., 1986).

In addition to these factors, the significance of crystalluria is determined by the type of crystal, the medical history of the animal, and the persistence of crystalluria in serial urinalyses. As implied previously, the presence of crystalluria does not necessarily warrant a change in diet or the administration of medication. Based on review of all available information, the clinician must determine the likelihood of stone formation in an individual animal. In male dogs or cats the clinician must also consider the risk of urethral obstruction. Crystalluria is more likely to be significant in animals with (1) known urolithiasis; (2) a prior history of urolithiasis or urinary obstruction; (3) clinical signs of lower urinary tract disease, or (4) persistent or particularly heavy crystalluria.

MANAGING CRYSTALLURIA

Bilirubin

Bilirubin crystals appear as yellow-red or red-brown needles or granules (Fig. 185-1). Bilirubin crystalluria can be normal in dogs (Reilly et al., 2001), especially in concentrated urine; however, these crystals are always abnormal in cats. Bilirubin crystalluria may occur with diseases associated with hyperbilirubinemia and bilirubinuria, including prehepatic, hepatic, and posthepatic causes.

Fig. 185-1 Bilirubin crystals. (Photomicrograph courtesy Dr. India Lane, The University of Tennessee.)

Calcium oxalate

Calcium oxalate crystals (Fig. 185-2) may occur with urolith formation but also with diseases associated with hypercalcemia (e.g., hyperparathyroidism or neoplasia) or with ethylene glycol toxicity (usually these crystals are calcium oxalate monohydrate). Presence of calcium oxalate crystalluria should prompt evaluation of the patient for a predisposing disease, especially if hypercalcemia is present. As with other crystals, the presence of calcium oxalate crystalluria is not synonymous with urolith formation, nor does the absence of calcium oxalate crystalluria rule out urolithiasis. Over 50% of dogs and cats with active calcium oxalate urocystolithiasis do not have crystalluria (Osborne et al., 1996). If calcium oxalate crystalluria is persistent and other diseases have been ruled out, preventive strategies should be considered. Several diets are available for managing calcium oxalate urolithiasis in dogs and cats. In addition, potassium citrate administration may be beneficial as an alkalinizing agent; citrate is a calcium oxalate inhibitor. Thiazide diuretics decrease urinary calcium excretion in dogs and are used in humans with idiopathic hypercalciuria and calcium oxalate urolithiasis; however, there are no long-term studies in dogs and cats evaluating their efficacy or safety.

Cystine

Cystine crystals typically occur in urine with a pH less than 7.0 (Fig. 185-3). Cystine urolithiasis occurs uncommonly—in fewer than 2% of dogs and fewer than 0.2% of cats. Cystine is a disulfide-containing amino acid and is normally filtered at the glomerulus and resorbed in the proximal tubule. Therefore cystinuria and cystine crystalluria occur because of a defect in resorption in the proximal renal tubule. Management of cystine crystalluria and urolithiasis involves feeding a low-protein diet (since cystine is an amino acid), increasing urine volume (decreasing urine specific gravity), and increasing urine pH. Because cystine solubility increases exponentially when the urine pH is greater than 7.2, urine alkalization to 7.5 is recommended.

**A****B**

Fig. 185-3 Cystine crystals.

Pharmacologically cystine crystalluria can be decreased by administering a drug that cleaves the disulfide bond, resulting in a more soluble compound. These drugs include D-penicillamine and 2-mercaptopyrionylglycine (2-MPG). 2-MPG is associated with fewer side effects.

Struvite

Struvite crystals occur commonly in dogs and cats, and struvite is the most common mineral occurring in uroliths from dogs and cats. Struvite crystals typically form in concentrated urine that has a pH greater than 7.0 in the dog and greater than 6.5 in the cat (Fig. 185-4). Two types of struvite uroliths occur: infection-induced and sterile. Infection-induced struvite uroliths occur most commonly in dogs, in pediatric dogs and cats, and in animals that are immunocompromised. For infection-induced struvite stones to form, the microbe must produce urease, which is an enzyme that metabolizes urea, resulting in oversaturation of urine. Therefore struvite crystalluria in dogs that do not have a urinary tract infection is rarely a concern and requires no treatment. Adult cats typically form struvite uroliths without a urinary tract infection (sterile struvite uroliths); therefore struvite crystalluria is more of a clinical concern in an adult cat. This is particularly true in male cats because greater than 80% of urethral matrix-crystalline plugs contain struvite as the predominant mineral (Lekcharoensuk et al., 2002). Management of struvite crystalluria in cats involves increasing urine volume (decreasing urine specific gravity) and feeding a diet that is formulated to contain lower quantities of magnesium, protein (source of ammonium), and phosphate and that induces an acidic pH. Therapeutic foods are available for both struvite dissolution and struvite prevention.

Uric Acid

Uric acid or urate salts (ammonium or sodium) usually occur in acid urine. They are often yellow or yellow-brown and may occur in a variety of shapes (Fig. 185-5). Uric acid crystalluria occurs uncommonly except in Dalmatians and English bulldogs that have a breed-associated crystalluria and urolithiasis. Uric acid crystalluria may occur in animals with hepatic disease, especially portosystemic shunts. For this reason, liver function should be evaluated in dogs and cats with uric acid crystalluria. If uric

Fig. 185-5 Ammonium urate crystals.

acid crystalluria is associated with liver disease, managing the underlying liver disease may help prevent urolith formation.

In dogs and cats with no underlying hepatic dysfunction (e.g., Dalmatians), crystalluria may or may not lead to urolith formation. Persistent crystalluria, especially with concentrated urine, increases the risk for urolith formation. Dietary manipulation to reduce protein consumption and induce alkaline urine is often sufficient to minimize uric acid crystallization. Allopurinol, a xanthine oxidase inhibitor that competitively inhibits the conversion of xanthine to uric acid, may be required in dogs in which dietary therapy is not completely effective. Allopurinol therapy has not been evaluated in cats, although it has been used.

Xanthine

Xanthine crystals (Fig. 185-6) occur rarely in dogs and cats unless they are receiving allopurinol, a xanthine oxidase inhibitor that inhibits the metabolic conversion of xanthine to uric acid. Concurrent consumption of a nonprotein-restricted diet increases the risk of xanthine crystalluria and urolithiasis in dogs and cats receiving allopurinol. Higher-protein foods increase the dietary intake of urate precursors and thereby increase xanthine levels. Naturally occurring xanthinuria and xanthine crystalluria have been described in cavalier King Charles spaniels (van Zuilen et al., 1997) and cats (Osborne et al., 2004). Xanthine crystalluria represents an increased risk for xanthine urolith formation. Treatment involves feeding a restricted protein diet, inducing production of more dilute urine, and urinary alkalization.

Crystalluria occurs commonly in dogs and cats and represents renal excretion of ions in a given urine sample. It may occur normally in healthy animals and does not necessarily imply that a pathologic condition is present or that uroliths will form. The significance of crystalluria should be interpreted in association with other historical, physical examination, laboratory, and imaging

Fig. 185-6 Xanthine crystals.

information. Understanding factors associated with crystal type and when and how crystals form helps to determine the significance of the crystalluria and the need, if any, for medical therapy.

Diagnostic Approach to Acute Azotemia

JENNIFER E. STOKES, *Knoxville, Tennessee*

GENERAL INFORMATION

Acute azotemia occurs as a result of rapid hemodynamic, filtration, tubulointerstitial, or excretory damage to the upper and/or lower urinary tract. The abrupt decrease in glomerular filtration rate (GFR) results in accumulation of uremic toxins and metabolic byproducts; metabolic dysfunction; and dysregulation of fluid, electrolyte, and acid-base balance. Because kidneys receive 20% of cardiac output, these organs are particularly susceptible to ischemic and toxicant-induced damage. Acute azotemia can develop as a result of prerenal, intrinsic renal, or postrenal disease.

Prerenal disease develops when GFR declines because of decreased renal blood flow or increased renal vascular resistance. Prerenal azotemia is a functional abnormality that is potentially reversible. Prerenal disease can coincide with intrinsic renal failure; and prolonged prerenal azotemia can progress to structural damage and intrinsic, irreversible renal failure. Patients with prerenal azotemia generally have concentrated urine (specific gravity >1.025), unless an underlying condition (Addison's disease) or concurrent medications (prednisone, furosemide) prevent maximal concentrating ability. Intrinsic causes of acute azotemia result from renal parenchymal damage caused by ischemic, glomerular, or tubular disease. In dogs and cats toxic, infectious, and ischemic causes occur most commonly. Postrenal azotemia is caused by obstruction or rupture of the urinary tract. If postrenal acute renal failure is recognized and treated early, most cases are reversible (see Chapter 191).

Establishing the cause of acute azotemia can help predict prognosis and determine if specific therapy is indicated in addition to standard supportive care. Specific medical treatments for some causes of acute azotemia include antimicrobials for leptospirosis and bacterial pyelonephritis and 4-methylpyrazole or ethanol for ethylene glycol (EG) toxicity (see Chapter 29). Prognosis for acute azotemia is variable and associated with the underlying cause. Animals with EG nephrotoxicity have a survival of 20% or less compared to the overall survival rate of acute renal disease of approximately 60% (Cowgill and Francey, 2005). Differential diagnoses for acute azotemia, including potential nephrotoxins and potential predisposing factors, are listed in Boxes 186-1 and 186-2.

DIAGNOSTIC PLAN FOR ACUTE RENAL AZOTEMIA

Signalment

During initial assessment the signalment may provide insight to the possible cause of acute azotemia. In general, young animals are more prone to dietary indiscretion; owners should be asked if their pet had access to zinc (pennies, bolts), lilies, raisins, grapes, or any medications. Congenital renal disease typically manifests as a chronic condition rather than as acute azotemia and is not discussed further. Neoplasia should be considered in geriatric patients, although lymphoma and nephroblastoma are encountered in the middle-aged and young pet. Urolithiasis is more common in certain breeds (Table 186-1) (see Chapter 203).

History

A thorough patient history assists in determining the cause of acute azotemia. The pet's current and past medical history should be reviewed for concurrent medical diseases, episodes of urolithiasis, urinary tract infection, recent sedation, or anesthesia. The pet's usual environment, travel history, and exposure to wild or domestic animals and ticks influences decisions concerning testing for infectious diseases. If leptospirosis is suspected, an accurate vaccine history must be collected since multivalent leptospiral vaccines are available.

The owner should be asked about the pet's exposure to *specific* nephrotoxins, as well as specific medications (see Box 186-1). Nonsteroidal antiinflammatory agents and angiotensin-converting enzyme inhibitors are the most commonly prescribed of the potentially nephrotoxic agents. In addition to medications prescribed for the pet, it is useful to determine if the pet has access to an owner's medications, such as oral medications with potential nephrotoxicity like topical zinc oxide or calcipotriol (a topical synthetic cholecalciferol antipsoriasis medication) (Welch, 2002). The possibility of recent exposure to antifreeze, cholecalciferol rodenticides, or toxic plants should be established. For many potential nephrotoxins, including raisins/grapes and lilies, determining their role in causing acute azotemia is usually made based on history.

Box 186-1

Potential Nephrotoxins Encountered in Small Animal Practice**Medications**

- Antimicrobial agents
 - Aminoglycosides
 - Amphotericin B
 - Carbapenems
 - Cephalosporins
 - Fluoroquinolones
 - Penicillins
 - Rifampin
 - Sulfonamides
 - Tetracyclines
 - Vancomycin
- Immunosuppressants
 - Azathioprine
 - Cyclosporine
 - Cancer chemotherapy
 - Bisphosphonates
 - Carboplatin
 - Cisplatin
 - Doxorubicin
 - Methotrexate
- Miscellaneous medications
 - Acyclovir
 - Angiotensin-converting enzyme inhibitors
 - Allopurinol
 - Apomorphine
 - Calcium
 - Cimetidine
 - Dextran 40
 - Mannitol
 - Nonsteroidal antiinflammatory drugs
 - Penicillamine
 - Streptokinase
 - Thiactetarsemide
 - Vitamin D (cholecalciferol)

Additional Substances

- Ethylenediaminetetraacetic acid
- Ethylene glycol
- Radiocontrast media
- Grapes, raisins
- *Lilium* spp.
 - Easter lily, tiger lily, stargazer lily, Asiatic hybrid lily
- *Heimerocallis* spp.
 - Common day lily, early day lily
- Heavy metals
 - Mercury, gold, nickel, thallium, lead, zinc
- Carbon tetrachloride
- Snake and bee venom
- Hemoglobin, myoglobin
- *Amanita phalloides* (mushroom)

Evidence of a specific toxin may be observed in the vomitus. Although a nephrotoxic substance has been extracted from Easter lilies, there is no commercial diagnostic test for this toxin; and the toxic agent of other lilies, raisins, and grapes is unknown (Rumbeiha et al., 2004).

Box 186-2

Potential Causes and Risk Factors for Acute Azotemia in Dogs and Cats**Vascular or Ischemic**

- Anesthesia
- Cutaneous and renal glomerular vasculopathy ("Alabama rot")
- Decreased cardiac output
- Dehydration
- Disseminated intravascular coagulation
- Hyperviscosity syndrome
 - Hyperglobulinemia
 - Multiple myeloma
 - Polycythemia
- Hypotension
- Surgery
- Systemic arterial hypertension
- Thrombosis/infarction
- Vasculitis

Concurrent administration of potential nephrotoxins (see Box 186-1)**Infectious**

- Bacterial and fungal pyelonephritis
- Leptospirosis
- Babesiosis
- Borreliosis
- Leishmaniasis

Metabolic/Systemic Disease

- Acidosis
- Diabetes mellitus
- Hepatic insufficiency
- Hyperadrenocorticism
- Hypercalcemia
- Hypoadrenocorticism
- Hypoalbuminemia
- Hypocalcemia
- Hypokalemia
- Hypomagnesemia
- Hyponatremia
- Pancreatitis
- Pre-existing renal disease
- Sepsis

Other

- Advanced age
- Immune-mediated disease
 - Acute glomerulonephritis
 - Renal transplant rejection
 - Systemic lupus erythematosus
- Urolithiasis
- Urinary tract rupture
- Envenomation
- Hyperthermia
- Neoplasia, infiltrative
- Tumor lysis syndrome (some causes can be placed under multiple categories)

Table 186-1

Breeds at Increased Risk of Urolithiasis (Canine Unless Otherwise Indicated)

Stone type	Breed
Calcium oxalate	Miniature schnauzers, Lhasa apso, Yorkshire terrier, bichon frise, Pomeranian, Shih Tzu, cairn terrier, Maltese, miniature poodle, Chihuahua
Calcium oxalate (feline)	Domestic shorthair, Himalayan, Persian, rag doll, British shorthair, exotic shorthair, Havana brown, Scottish fold
Struvite (magnesium ammonium phosphate)	Miniature schnauzers, Lhasa apso, Yorkshire terrier, Shih Tzu, bichon frise, miniature poodle, cocker spaniel
Urate/xanthane	Dalmatian, English bulldog, miniature schnauzer, Shih Tzu, Yorkshire terriers
Cystine	Mastiff, Australian cattle dog, English bulldog, dachshund, Staffordshire bull terrier, Newfoundland
Calcium phosphate	Yorkshire terrier, miniature schnauzer, bichon frise, Shih Tzu, springer spaniel, Pomeranian, miniature poodle, cocker spaniel
Silica	German shepherd, Old English sheepdog, cocker spaniel, bichon frise, Labrador retriever, golden retriever, miniature schnauzer, Shih Tzu

An accurate description of the current illness is important as well, including the duration of clinical signs and the specific nature of the clinical syndrome. A pet with signs of illness for several months' duration may have an acute exacerbation of chronic kidney disease. Dysuria, stranguria, and pollakiuria suggest lower urinary tract disease. Pets with a history of recent trauma may have uroabdomen or other renal or postrenal injury.

Physical Examination

A thorough physical examination should include routine evaluation, assessment of hydration status, and general body condition; a digital rectal examination; and an ophthalmic examination. Anterior uveitis is common with leptospirosis but may be present in animals with other infectious diseases or lymphoma. Leptospirosis should also be suspected in any icteric dog with acute azotemia (see Chapter 269). If pallor and red urine are present, intravascular hemolytic anemia from zinc intoxication or babesiosis should be considered. Infectious diseases should be ruled out in a febrile patient. Bradycardia should prompt investigation for hypoadrenocorticism, although bradycardia can be caused by hyperkalemia or excessive vagal tone from other causes. If dysphoria is present, further questioning of the owner and testing for EG toxicity are indicated. Cranial abdominal pain is a nonspecific finding but should increase one's index of suspicion of pancreatitis, particularly in dogs. If abdominal fluid is detected, diagnostic procedures should be done to rule uroabdomen in or out.

The kidneys should be palpated to determine renal size, symmetry, and pain. Finding small kidneys would suggest chronic renal disease with an acute exacerbation. Bilaterally large kidneys are palpated in animals with acute renal disease because of toxicity, infection, or lymphoma. The finding of frequently asymmetric kidneys (one large and one small) in a cat should prompt the clinician to assess the cat more closely for ureteral obstruction.

Local cellulitis may be consistent with envenomation from snake or bull ant bites. Generalized lymphadenomegaly should prompt a clinician to assess the pet more closely for lymphosarcoma or infectious diseases. If the pet has a poor body condition suggesting a chronic disease process, it is important to determine if chronic renal disease or hypoadrenocorticism is present. In animals with lower urinary tract signs, the lower urogenital area should be examined closely to assess for obstructive lesions. Urolithiasis or neoplasia may be suspected if urethral or anal gland masses, urethral thickening, or enlarged intrapelvic lymph nodes are palpated on digital rectal examination.

Initial Diagnostic Testing

If there are no definitive historical or physical examination findings to guide initial diagnostic testing, a complete blood count, serum biochemistry profile, electrolytes, urinalysis, urine culture, abdominal radiographs, and abdominal ultrasound should be performed. Leptospirosis testing is recommended in any dog with acute azotemia. Testing cats for feline leukemia and feline immunodeficiency virus may be indicated. Neither disease directly causes acute azotemia, but each may predispose to neoplasms or infections that adversely affect renal function. If available, measuring systemic blood pressure, blood gas values, and coagulation status can provide useful information, particularly for acute and long-term management.

Evaluation of Complete Blood Count

A clinician should be suspicious of leptospirosis, pyelonephritis, or other infectious disease if a leukocytosis and left shift are diagnosed. Testing for babesiosis and zinc intoxication are indicated if a strongly regenerative anemia is observed since both conditions cause intravascular hemolysis. Thrombocytopenia may be seen with leptospirosis, babesiosis, and rickettsial diseases. Hyperviscosity syndrome would be suspected in a patient with polycythemia or hyperglobulinemia. Relative polycythemia (hemoconcentration) may be evident in a pet with prerenal azotemia. Absolute polycythemia may be present as a result of polycythemia vera or secondary polycythemia caused by chronic hypoxemia or a paraneoplastic syndrome (e.g., renal neoplasia).

A sick azotemic animal with a lack of a stress leukogram or relative eosinophilia should be tested for hypoadrenocorticism (adrenocorticotrophic hormone stimulation test). *Babesia* organisms may be seen on peripheral blood smears, but an absence of hemoparasites does not rule out such an infection, and serologic testing is indicated in suspect cases.

Evaluation of Serum Biochemical Results

Further diagnostic tests are indicated in hypercalcemic animals (also see Chapter 54). Hypercalcemia is most commonly caused by neoplasia, chronic renal failure, hypoadrenocorticism, hyperparathyroidism, and vitamin D toxicosis in dogs. In cats neoplasia, renal disease, and idiopathic hypercalcemia are the most common causes of elevated serum total calcium. Hypercalcemic animals should have ionized calcium and ideally blood pH measurements performed. Hypercalcemia-induced acute azotemia is most commonly associated with neoplasia, vitamin D toxicosis, and primary hyperparathyroidism. Hypoglycemia may suggest sepsis or hypoadrenocorticism in an azotemic patient. Hyperkalemia with concurrent hyponatremia may be caused by hypoadrenocorticism, acute renal failure (of any cause), and uroabdomen. Elevations in liver enzyme activity, bilirubin concentration, or creatinine kinase activity should increase the clinician's index of suspicion for leptospirosis. In dogs elevated amylase and lipase suggest pancreatitis but are not specific markers for the disease. Currently the most sensitive laboratory test for pancreatitis in cats is a species-specific pancreatic lipase immunoreactivity test (see Chapter 124).

Hypocalcemia occurs in 50%, and hyperglycemia occurs in more than 70% of cats and dogs with EG intoxication. Marked acidosis and elevated anion gap (Gaynor and Dhupa, 1999) also should increase suspicion for EG intoxication. Acidosis can be estimated by assessing serum total carbon dioxide levels, although measuring blood pH is preferable. Hyperphosphatemia can also occur because of the presence of phosphate-containing rust inhibitors in EG.

Urinalysis

A urinalysis should be performed in all azotemic patients. Leptospirosis has been associated with glucosuria, proteinuria, bilirubinuria, increased granular casts, leukocytes, and erythrocytes. Leptospire are not observed in urine without special staining or dark-field microscopy. Crystalluria occurs in healthy animals but may be associated with urolithiasis (see Chapter 185). Both dihydrate and monohydrate calcium oxalate crystals (especially the latter) may be observed in EG cases, although both can be seen in normal animals. Pyelonephritis should be suspected when pyuria, hematuria, and increased granular casts are present; however, absence of bacteriuria does not rule out upper urinary tract infection. Yeast or fungi may be seen cytologically. Urine culture is indicated in all patients with acute azotemia.

Imaging Studies

Routine abdominal imaging is also indicated in dogs and cats with acute azotemia. Survey abdominal radiography is useful in determining renal size and detecting uroliths, abdominal fluid, metallic gastrointestinal foreign bodies, mass lesions, and bony trauma. Severe vitamin D toxicosis may be suspected if generalized soft-tissue mineralization is seen radiographically. Contrast studies (excretory urography or cystourethrography) are

the most sensitive methods for detecting urinary tract rupture.

Abdominal ultrasound is extremely useful for assessing the structure of the urinary tract and surrounding tissues. Sonography may detect renal cysts or masses, abdominal fluid, uroliths, hydronephrosis, outflow obstruction, pancreatitis, lymphadenomegaly, bilaterally small adrenal glands, and abdominal masses. Doppler techniques can be used to assess for renal vascular changes such as thromboemboli and occlusive mass lesions. Specific sonographic renal abnormalities detected in dogs with leptospirosis include renomegaly, pyelectasia, hyperechoic cortices, perirenal fluid accumulation, and a hyperechoic medullary band, which corresponds to necrosis and hemorrhage (Greene et al., 2006). Sonographic abnormalities reported in dogs and cats with known or probable EG toxicity include hyperechoic renal cortices and medulla, which can progress to severe intensity, and a "halo" sign, which is a band of relative hypoechogenicity at the corticomedullary junction and central medulla surrounded by hyperechoic cortex and medulla. The changes vary, depending on the stage of toxicity (Adams, Toal, and Breider, 1991).

Imaging studies also are critical for the detection of ureteral obstruction. Radiographic abnormalities documented in cases of ureteral obstruction in cats include bilateral renomegaly, renal asymmetry, expansion of the retroperitoneal space, or ureteroliths. Radiography or ultrasonography may diagnose ureteral obstruction, but in 20% to 30% of cats no discrete mineralized material is identified with routine abdominal imaging. The sensitivity for detecting ureteroliths increases when radiographs and serial ultrasound examinations are used in tandem (see Chapter 202). Antegrade pyelography using ultrasound guidance to inject contrast media into the renal pelvis can be performed to detect and characterize ureteral obstructions that are not apparent with routine radiographic techniques (Kyles et al., 2005). Advanced imaging techniques (such as computed tomography or urethrocystoscopy) are sometimes required in challenging cases of ureteral obstruction or other unusual types of acute azotemia.

When To Consider a Renal Biopsy

Renal biopsy occasionally is indicated for determining the underlying cause of disease and prognosis in a patient with acute azotemia. It should be considered if the definitive cause, extent of injury, chronicity, or prognosis cannot be established by less invasive means. It is also recommended in patients for which peritoneal dialysis or hemodialysis is considered. Histologic evidence of intact renal tubular epithelial basement membranes and regenerating epithelial cells are favorable indicators for recovery. Renal tissue samples also can be analyzed for EG content. Calcium oxalate crystals may be seen histologically, although crystals are not pathognomonic for EG toxicity. Leptospirosis may also be diagnosed histologically using Giemsa or silver stain in biopsy or postmortem tissue samples. Renal biopsy to diagnose leptospirosis usually is indicated in determining zoonotic potential for

exposed people and pets rather than as a means of determining an antemortem clinical diagnosis.

Additional Diagnostic Tests

Infectious Disease Testing

As mentioned previously, leptospirosis is a key differential diagnosis for acute renal azotemia. The standard serologic test for leptospirosis is the microscopic agglutination test (MAT). It is serogroup specific but not serovar specific. Testing for multiple serovars, including canicola, icterohaemorrhagiae, bratislava, hardjo, pomona, grippityphosa, and autumnalis is recommended. Ideally serologic diagnosis of leptospirosis is based on a fourfold increase in paired titers completed at a 2- to 4-week interval. Dogs can be seronegative the first seven to ten days of clinical illness. A single titer of 1:800 can be used to support a presumptive diagnosis of leptospirosis when compatible clinical disease is present and there is no history of leptospiral vaccination within the previous 3 months. Vaccine titers usually are less than 1:400 for the first 3 months after vaccination, but titers as high as 1:800 have been observed to persist for 9 months after vaccination. An immunoglobulin M enzyme-linked immunosorbent assay (ELISA) is more sensitive in detecting early infection than the MAT but is not yet widely available for clinical use.

In addition to serologic testing, it is also useful to submit urine for polymerase chain reaction (PCR) tests for leptospiral organisms. Although organisms may not be shed in urine for 4 to 10 days after onset of illness and antimicrobial therapy may decrease renal shedding, urinary PCR is highly sensitive (perhaps oversensitive) for leptospirosis. The presence of leptospiral organisms in the urine (based on PCR results), and clinical findings compatible with leptospirosis, the dog should be considered a potential zoonotic source of disease for humans (Greene et al., 2006).

Babesiosis is a rare cause of acute azotemia in dogs, but it should be considered in a dog with acute azotemia and regenerative anemia and/or thrombocytopenia. Indirect fluorescent antibody testing is probably the most specific and commonly used test to detect *Babesia* antibodies. Usually a titer of $\geq 1:80$ to *B. canis* or $\geq 1:320$ to *B. gibsoni* is sufficient for diagnosis (Taboada and Lobetti, 2006). Dogs may be seronegative early in the disease; thus measuring convalescent titers is necessary in some cases to make a diagnosis. PCR testing is also available and is the most sensitive and specific means of diagnosis.

Although acute azotemia has not been proven to be a result of infection with *Borrelia burgdorferi* in dogs, there is an association between Lyme disease and acute azotemia. In dogs in Lyme-endemic areas that develop a progressive, proteinuric form of acute azotemia, testing for borreliosis is recommended. The most common screening procedures include ELISA and indirect fluorescent antibody techniques, but false-positives caused by cross-reactivity with other organisms or to vaccination occur. Any such positive result should be followed by a confirmation test such as Western blot or an ELISA test for antibodies against specific proteins (recombinant Osp C or C6). A commercial test, SNAP 3DX (IDEXX Laboratories) is available for testing for antibody to the C6 peptide and

is likely the most sensitive and specific test to diagnose active infection (as opposed to recovered infection or vaccine or cross-reactivity). Dogs can be seropositive and not be ill from infection; thus diagnosis should not be made on serologic testing alone (Greene and Straubinger, 2006).

Evaluation of Abdominal Fluid

If present, abdominal fluid should be collected for fluid analysis and cytologic examination. A sample should be saved for future culture. Fluid protein should be measured. Fluid potassium, creatinine, and urea nitrogen should be measured and compared to serum values to diagnose or rule out uroabdomen.

Ethylene Glycol Assays

Measuring serum or urine EG levels by gas chromatography is the most specific diagnostic test for EG toxicity, but such testing is not readily available. A commercially available test kit (Allelic Biosystems Ethylene Glycol Test Kit, PRN Pharmacal, Inc.) measures blood EG concentrations of 50 mg/dl or above. Levels are highest 3 hours after ingestion and are nondetectable within 48 hours of ingestion. This test is most useful 1 to 12 hours after ingestion but may detect EG for up to 24 hours or longer after exposure since EG is excreted slowly in acute renal failure. The test may be falsely negative in cats, which can develop acute azotemia at lower serum EG levels. False-positive results occur in animals exposed to glycerol, met-aldehyde, and propylene glycol (e.g., anticonvulsants, activated charcoal) (Gaynor and Dhupa, 1999).

Zinc Assays

A presumptive diagnosis of zinc toxicity is made in an azotemic, anemic patient with evidence of a metallic gastrointestinal foreign body. Zinc is a common element in United States pennies (minted after 1982), cage nuts, cage wire, brass buttons, and zinc oxide ointment. Diagnosis is confirmed by measuring plasma zinc levels. Correct sample collection is imperative; many ethylenediaminetetraacetic acid and heparin collection tubes contain zinc in their rubber stoppers, which may contaminate the sample. Royal blue-top tubes are zinc free. Assessment of tissue levels in the liver or kidney may also be diagnostic.

CHAPTER 187

Proteinuria: Implications for Management

GREGORY F. GRAUER, *Manhattan, Kansas*

Persistent proteinuria of renal origin is an important marker of chronic kidney disease (CKD) in both dogs and cats. Albumin is usually the primary component of proteinuria in CKD. Not only is proteinuria a diagnostic marker for CKD, but the potential for proteinuria/albuminuria to mediate CKD progression has also been recognized. The recent development of species-specific albumin enzyme-linked immunosorbent assay technology has enabled detection of low concentrations of canine and feline albuminuria. This advance has stimulated discussion of what levels of proteinuria/albuminuria are normal and what values may be associated with renal disease progression. For these reasons detection, monitoring, and treatment of dogs and cats with renal proteinuria have received renewed interest. Just as our definition and treatment guidelines for systemic hypertension are changing, so perhaps is our approach to recognizing, monitoring, and treating proteinuria.

DETECTION OF PROTEINURIA

Proteinuria is routinely detected by semiquantitative screening methods such as the conventional dipstick colorimetric test (very common) and the sulfosalicylic acid (SSA) turbidimetric test (less common). The dipstick test is inexpensive, easy to use, and primarily measures albumin; however, both the sensitivity and specificity for albumin are relatively low with this methodology. False-positive results (decreased specificity) may be obtained if the urine is alkaline, if the urine sediment is active (pyuria, hematuria, and/or bacteriuria; often termed *postrenal* proteinuria), or if the dipstick is left in contact with the urine

long enough to leach out the citrate buffer that is incorporated in the filter paper pad. False-positive results with the dipstick occur more frequently in cats than in dogs but occur in both. False-negative results (decreased sensitivity) may occur in the setting of Bence Jones proteinuria, low concentrations of albuminuria, and/or dilute or acidic urine. The conventional dipstick test has a detection level of greater than 30 mg/dl.

The SSA test is performed by mixing equal quantities of urine supernatant and 5% SSA in a glass test tube and grading the turbidity that results from precipitation of protein on a 0 to 4+ scale. In addition to albumin, the SSA test can detect globulins and Bence Jones proteins. False-positive results may occur if the urine contains radiographic contrast agents, penicillin, cephalosporins, sulfisoxazole, or the urine preservative thymol. The protein content may also be overestimated with the SSA test if uncentrifuged, turbid urine is analyzed. False-negative results are less common than with the conventional dipstick test because of the increased sensitivity of the SSA test (>5 mg/dl). Because of the relatively poor specificity of the conventional dipstick analysis, many reference laboratories confirm a positive dipstick test result for proteinuria with the SSA test. Still, grading of both the color change on the dipstick test and the turbidity on the SSA test is subjective; results can vary among individuals and laboratories.

Proteinuria detected by these semiquantitative screening methods has historically been interpreted in light of the urine specific gravity and urine sediment. For example, a positive dipstick reading of trace or 1+ proteinuria in hypersthenuric urine has often been attributed to

urine concentration rather than abnormal proteinuria. In addition, a positive dipstick reading for protein in the presence of hematuria or pyuria was often attributed to urinary tract hemorrhage or inflammation. In both examples the interpretation may not be correct. Given the limits of the conventional dipstick test sensitivity, any positive result for protein regardless of urine concentration may be abnormal (except in the case of false-positive results). Likewise, hematuria and pyuria have an inconsistent effect on urine albumin concentrations; not all dogs with hematuria and pyuria have albuminuria.

DETECTION OF ALBUMINURIA

Albuminuria can be measured by point-of-care, semi-quantitative tests (e.g., E.R.D.-HealthScreen Urine Test, Heska Corporation) and with quantitative immunoassays at reference laboratories. Microalbuminuria (MA) is defined as concentrations of albumin in the urine that are greater than normal but below the limit of detection using conventional dipstick urine protein screening methodology. Because of the sensitivity of the conventional dipstick test, the upper end of urine albumin concentration that is considered to represent MA is 30 mg/dl. Urine albumin concentrations above 30 mg/dl are referred to as overt albuminuria and can often be detected using the urine protein/creatinine (UP/C) ratio (see Quantitation of Proteinuria later in the chapter). The lower end of the MA range has been less easily defined because of the requirement that this concentration be greater than “normal” and the necessity that this concentration be reliably detected. In the dog and cat the lower limit was defined based on the log mean + 2 standard deviations of populations of apparently healthy dogs and cats as greater than 1 mg/dl. Urine albumin concentrations can be adjusted for differences in urine concentration by dividing by urine creatinine concentrations. For example, a urine albumin/creatinine ratio greater than 0.03 is considered abnormal in humans. Alternatively urine can be diluted to a standard concentration such as 1.010 before assay. In one study of dogs normalizing urine albumin concentrations to a 1.010 specific gravity yielded similar results to the ratio of urine albumin/creatinine (Lees et al., 2002).

Indications for the use of MA tests include: (1) when conventional screening tests for proteinuria produce equivocal or conflicting results or false-positive results are suspected; (2) when conventional screening tests for proteinuria are negative in apparently healthy older dogs and cats and a more sensitive screening test is desired; (3) when conventional screening tests for proteinuria are negative in apparently healthy young dogs and cats with a familial risk for developing proteinuric renal disease and a more sensitive screening test is desired; or (4) when conventional screening tests for proteinuria are negative in dogs and cats with chronic illnesses associated with a high risk for proteinuric renal disease and a more sensitive screening test is desired.

LOCALIZATION OF PROTEINURIA

When proteinuria is detected by screening tests, it is important to try to identify its source. Proteinuria may

be caused by physiologic or pathologic conditions. Physiologic or benign proteinuria is often transient and abates when the underlying cause is corrected. Strenuous exercise, seizures, fever, exposure to extreme heat or cold, and stress are examples of conditions that may cause physiologic proteinuria. The mechanism of physiologic proteinuria is not completely understood; however, transient renal vasoconstriction, ischemia, and congestion may be involved. Decreased physical activity may also affect urine protein excretion in dogs; one study showed that urinary protein loss was higher in dogs confined to cages than in dogs with normal activity levels (McCaw, Knapp, and Hewet, 1985).

Pathologic proteinuria may be caused by urinary or nonurinary abnormalities. Nonurinary disorders associated with proteinuria often involve the production of small-molecular weight proteins (dysproteinemias) that are filtered by the glomeruli and subsequently overwhelm the resorptive capacity of the proximal tubule. An example of this “prerenal” proteinuria is the production of immunoglobulin light chains (Bence Jones proteins) by neoplastic plasma cells. Genital tract inflammation (e.g., prostatitis or metritis) can also result in pathologic nonurinary proteinuria. Obtaining urine samples via cystocentesis reduces the potential for urine contamination with protein from the lower urinary tract.

Pathologic urinary proteinuria may be renal or nonrenal in origin. Nonrenal proteinuria most frequently occurs in association with lower urinary tract inflammation or hemorrhage (also referred to as postrenal proteinuria). Changes observed in the urine sediment are usually compatible with the underlying inflammation (e.g., pyuria, hematuria, bacteriuria, and increased numbers of transitional epithelial cells). On the other hand, renal proteinuria is most often caused by increased glomerular filtration of plasma proteins associated with intraglomerular hypertension, glomerular capillary wall structural abnormalities, or the presence of immune complexes or vascular inflammation in the glomerular capillaries. Renal proteinuria may also be caused by decreased resorption of filtered plasma proteins caused by tubulointerstitial disease. In some cases tubulointerstitial proteinuria may be accompanied by normoglycemic glucosuria and increased excretion of electrolytes (e.g., Fanconi syndrome and acute tubular damage). Glomerular lesions usually result in higher-magnitude proteinuria compared with proteinuria associated with tubulointerstitial lesions. In addition to glomerular and tubulointerstitial disease, renal proteinuria may be caused by inflammatory or infiltrative disorders of the kidney (e.g., neoplasia, pyelonephritis, and leptospirosis), which are often accompanied by an active urine sediment.

MONITORING RENAL PROTEINURIA

Transient renal proteinuria/albuminuria is likely of little consequence and does not warrant treatment. On the other hand, persistent renal proteinuria/albuminuria indicates the presence of CKD. Persistent proteinuria/albuminuria can be defined as positive test results on three or more occasions 2 weeks or more apart. Because persistent proteinuria/albuminuria can be constant or increase

or decrease in magnitude over time, monitoring should use quantitative methods to determine disease trends and/or response to treatment. Changes in the magnitude of proteinuria should always be interpreted in light of the patient's serum creatinine concentration since proteinuria may decrease in progressive renal disease as the number of functional nephrons decrease. Decreasing proteinuria in the face of a stable serum creatinine suggests improving renal function, whereas decreasing proteinuria in the face of an increasing serum creatinine suggests disease progression.

QUANTITATION OF PROTEINURIA

If persistent proteinuria is detected by screening tests, urine protein excretion should be quantified. This helps to evaluate the severity of renal lesions and to assess the response to treatment or the progression of disease. Methods used to quantitate proteinuria include the UP/C ratio and immunoassays for albuminuria that are expressed as either urine albumin/creatinine ratio or in milligrams per deciliter in urine samples that have been diluted to a standard urine specific gravity (e.g., 1.010). Albumin concentration of 30mg/dl or greater in urine standardized in this fashion usually results in UP/C ratios of 0.4 and 0.5 or greater in cats and dogs, respectively. The UP/C and urine albumin/creatinine ratios from spot urine samples have been shown to accurately reflect the quantity of protein/albumin excreted in the urine over a 24-hour period. Because of the difficulty of 24-hour urine collection, this methodology has greatly facilitated the diagnosis of proteinuric renal disease in veterinary medicine. Most studies have shown that normal urine protein excretion in dogs and cats is 10mg/kg/24 hours or less and that normal UP/C ratios are 0.2 to 0.3 or less. Initially recommended normal values for canine UP/C ratios of less than 1.0 were likely too liberal and have recently been lowered. Today UP/C ratios less than 0.5 and 0.4 are considered as normal for dogs and cats, respectively. Persistent proteinuria that results in UP/C ratios greater than 0.4 and 0.5 in cats and dogs, respectively, when prerenal and postrenal proteinuria have been ruled out, is consistent with either glomerular or tubulointerstitial CKD. Urine protein/creatinine ratios greater than 2.0 are strongly suggestive of glomerular disease. It is possible that the definition of normal will continue to change with additional research. For example, even the ultralow-level, single-nephron proteinuria that occurs secondary to intraglomerular hypertension in hypertrophied nephrons in CKD is abnormal in the face of what may be considered normal whole-body or whole-kidney proteinuria.

TREATMENT OF RENAL PROTEINURIA

Once persistent proteinuria has been documented by monitoring, the appropriate response depends on the magnitude of the proteinuria and the health status of the patient (e.g., the presence or absence of azotemia and/or hypertension). In nonazotemic, persistently proteinuric patients, further investigation (and appropriate treatment) of potential concurrent infectious,

inflammatory, or neoplastic diseases is warranted. For example, proteinuria associated with dirofilariasis in dogs often improves or resolves after successful treatment of the infection. Neoplasia, infection, polyarthrititis, hepatitis, hyperadrenocorticism, immune-mediated hemolytic anemia, and systemic hypertension are commonly identified concurrent medical problems in dogs with renal proteinuria. In cats viral diseases, neoplasia, immune-mediated disease, polyarthrititis, and systemic hypertension are some of the more common conditions associated with renal proteinuria. Unfortunately in many cases an underlying disease may not be identified or may be impossible to eliminate (e.g., neoplasia). In a retrospective study of over 100 dogs with glomerulonephritis, 43% had no identifiable concurrent disease. (Cook and Cowgill, 1996).

When an underlying disorder cannot be identified or treated, treatment strategies for persistent proteinuria depend on its magnitude. Proteinuria resulting in UP/C ratios greater than 1.0 to 3.0 should be treated, whereas continued monitoring and patient investigation should be the primary focus in cases with lesser-magnitude proteinuria. Treatment recommendations usually include reduced dietary protein (early renal failure diets), n-3 fatty acid supplementation (early renal failure diets), low-dose aspirin (0.5mg/kg q24h orally [PO]), and angiotensin-converting enzyme (ACE) inhibitors (e.g., enalapril, benazepril, 0.5 to 1 mg/kg q24h PO), although it is difficult to separate the effects of individual treatments when they are used in combination. The recommendation to treat proteinuria of this magnitude comes primarily from the results of a blinded, multicenter clinical trial in dogs with spontaneous glomerulonephritis. All dogs in this study had UP/C ratios 3.0 or higher, and all dogs were fed a renal failure diet and treated with low-dose aspirin in addition to either enalapril or placebo (Grauer et al., 2000). Therefore it is possible that the beneficial effects of ACE inhibitors observed in this study (1) would not be observed in dogs with lesser-magnitude proteinuria, and (2) were dependent on the concurrent dietary and aspirin treatment. In another study enalapril treatment, initiated before the onset of proteinuria and azotemia in male Samoyed dogs with X-linked hereditary nephritis, attenuated the eventual proteinuria and azotemia, decreased glomerular basement membrane splitting, and prolonged survival (Grodecki et al., 1997).

Treatment for persistent proteinuria in azotemic dogs and cats should be initiated when the UP/C is 0.5 and 0.4 or greater, respectively. Treatment recommendations in this case usually include ACE inhibition and renal failure diets. These recommendations come from (1) studies in dogs and cats with naturally occurring chronic renal failure (CRF) that document reduced survival associated with proteinuria (Jacob et al., 2005; Syme et al., 2006); and (2) studies in dogs with the remnant kidney model of CRF in which ACE inhibition and n-3 fatty acid supplementation reduced proteinuria and slowed renal disease progression (Brown et al., 1998, 2003). Additional management considerations for CKD are given in several chapters in this section, including Chapters 190 and 192.

SUPPORTIVE CARE

In addition to the previous considerations, supportive therapy is also important in the management of proteinuric renal disease. This supportive care should be aimed at decreasing hypertension, edema, and the tendency for thromboembolism to occur. Reduction of systemic hypertension may reduce intraglomerular hypertension, especially in dogs and cats with renal disease, that has resulted in loss of autoregulation of renal blood flow. Measurement of antithrombin III and fibrinogen concentrations may be helpful in determining which patients should be treated with anticoagulant therapy. Dogs with antithrombin III concentrations less than 70% of normal and fibrinogen concentrations greater than 300 mg/dl are candidates for therapy. Low-dose aspirin is easily administered on an outpatient basis and does not require extensive monitoring. Since fibrin accumulation within the glomerulus is a frequent consequence of proteinuric renal disease, aspirin treatment may serve a dual purpose. Finally, reduced-quantity, high-quality protein diets with n-3 fatty acid supplementation should also be recommended in an attempt to decrease glomerular hyperfiltration and proteinuria. For additional, specific treatment strategies for glomerular disorders, see Chapter 188.

CHAPTER 188

Glomerular Disease

SHELLY L. VADEN, *Raleigh, North Carolina*
CATHY A. BROWN, *Athens, Georgia*

Glomerular diseases are a leading cause of renal disease in dogs, but they occur less commonly in cats. The standard of care for management of dogs and cats with glomerular disease is nonspecific, but the standard of care in humans often includes additional therapy based on the histologic diagnosis of the glomerular disease. The recent movement to improve the evaluation of renal biopsy specimens from dogs and cats should eventually lead to implementation of disease-specific protocols for the treatment of dogs and cats with glomerular disease. The purpose of this chapter is to discuss the glomerular diseases that occur in dogs and cats, including specific management suggestions.

NONSPECIFIC MANAGEMENT OF GLOMERULAR DISEASE

Nonspecific management is indicated in all dogs and cats with glomerular disease, regardless of the histologic diagnosis. Nonspecific management can be divided into four major categories, based primarily on the stage of progression of chronic kidney disease (CKD) in an individual patient (see Chapter 192). The management categories are (1) treatment of potentially underlying diseases processes (CKD stages 1 to 4); (2) reduction of proteinuria (CKD stages 1 to 4); (3) modification of factors known to contribute to progression of renal disease (CKD stages 3 to 4); and (4) management

of uremia and other complications of generalized renal failure (CKD stages 3 to 4). Detailed discussions of each of these categories can be found in other chapters in this section. However, the need to evaluate an animal with persistent glomerular proteinuria for systemic diseases cannot be overemphasized. Many of the glomerular diseases that occur in dogs and cats are believed to develop secondary to a systemic *neoplastic*, *infectious*, or *noninfectious inflammatory disease process* (NIN). However, a NIN may not be obvious at first presentation because it is either resolved or occult. Because occult diseases may become overt months after initial presentation, continued observation and scrutiny are necessary. Identification and treatment of a NIN is the initial and perhaps most important step in the management of a persistently proteinuric dog or cat. The animal should be evaluated subsequently for resolving proteinuria, which may occur slowly over a period of months (see Chapter 187).

PROCUREMENT AND EVALUATION OF THE RENAL BIOPSY

Specimen Preparation

If proteinuria does not resolve or worsens over time or following treatment of a potentially underlying NIN, a renal biopsy to determine the specific glomerular disease present may be warranted. More study is needed to determine which dogs and cats with glomerular disease benefit the most from the results of a renal biopsy. However, it is likely that the animals with CKD stages 1 or 2 (possibly 3) and with magnitude of proteinuria that is either in or nearing nephrotic range are the ones that will benefit the most. Once collected, renal biopsy specimens should be divided into three pieces, each of which contains glomeruli. The largest piece should be placed in formalin, a smaller piece should go into a fixative suitable for electron microscopy (EM; e.g., 4% formalin plus 1% glutaraldehyde in sodium phosphate buffer), and another small piece should either be frozen or placed in a fixative suitable for immunofluorescent microscopy (IFM); (i.e., ammonium sulfate-N-ethylmaleimide fixative, also known as Michel's solution). Although light microscopy may be highly suggestive of a particular glomerular disease, particularly with more advanced disease, EM is required to verify the presence of immune deposits, to detect small deposits not evident by light microscopy, to identify the location of the deposits in the glomerulus (subendothelial, subepithelial, intramembranous, mesangial), and to detect basement membrane or podocyte abnormalities. IFM is used to determine the specific nature of the immune deposits (immunoglobulin [Ig]G, IgA, IgM, complement) and further defines the disease process.

Evaluation of Biopsy Specimens

The normal renal cortex contains scattered glomeruli and numerous tubules within a scant interstitium. These renal components are evaluated initially in slides stained with hematoxylin and eosin (H&E) to determine lesion distribution, severity, and the primary site of renal disease

(interstitial or glomerular). The evaluation of the glomeruli is the focus of this discussion; a description of the evaluation of the entire biopsy sample can be found elsewhere. The glomerulus is a tuft of highly branched capillaries that invaginate into an extension of the proximal tubule. The afferent arteriole enters and arborizes to form the glomerular capillary tuft and exits as the efferent arteriole; these arterioles enter and exit at the vascular pole. The capillary loops are supported by scaffolding that is made up of mesangial cells and their surrounding extracellular mesangial matrix. The capillary tuft is draped by glomerular basement membrane (GBM) and is covered by a layer of interdigitating visceral epithelial cells (podocytes). The glomerular filtration barrier consists of endothelium, GBM, and podocytes.

Proteinuria results when there is disruption of the filtration barrier, which may be caused by the deposition of immune complexes, complement, or amyloid; by a change (either acquired or congenital) in the composition of the GBM; or by injury to the endothelial cells or podocytes. Glomerular injury may also affect mesangial cells, resulting in mesangial cell proliferation and/or increased production of mesangial matrix. Since injury primarily affecting mesangial cells does not directly disrupt the filtration barrier, proteinuria is not typically a prominent feature of diseases involving mesangial cells. Glomerular involvement observed by light microscopy may be *focal* (less than 50% of glomeruli involved) or *generalized* (all or almost all glomeruli involved). Within an affected glomerulus, the lesion may be *segmental* (only part of the capillary tuft affected) or *global* (the entire tuft involved). Although most glomerular diseases in dogs and cats are generalized and global, focal segmental disease may also occur. Glomeruli should be evaluated for cellularity, matrix increase, amyloid deposition, hyalinization, necrosis, fibrin thrombosis, crescents, protein deposits, adhesions, and GBM changes. Because thicker sections appear more cellular, have more mesangial matrix, and have thicker capillary loops, renal biopsies should be routinely sectioned and evaluated at 3 to 4 μ m. Biopsies with glomerular deposits suggestive of amyloid should be cut at 6 to 8 μ m, stained with Congo red or standard toluidine blue, and viewed with polarized light to confirm this diagnosis. Periodic acid-Schiff hematoxylin (PASH) and Masson's trichrome stains, in addition to H&E, should be used when evaluating glomerular morphology in diseases other than amyloidosis. Basement membrane, mesangial matrix, and cell cytoplasm (including podocytes and endothelium) stain pink with PASH; trichrome stains basement membrane and mesangial matrix blue to blue-grey and immune deposits within the capillary walls magenta. In the normal glomerulus stained with PASH, the thickness of the capillary walls should be assessed in peripheral capillary loops; and, when cut at a right angle, the normal loops are thin, uniform, and crisp. The mesangial matrix can be seen as disconnected branches containing mesangial cells. Matrix typically surrounds one or two mesangial cell nuclei; mesangial matrix expansion is present if matrix extends to encircle more cells. More than three mesangial cell nuclei in close proximity are indicative of mesangial hypercellularity.

MEMBRANOPROLIFERATIVE GLOMERULONEPHRITIS

Glomerulonephritis is an immune-mediated disease most often associated with deposition of immune complexes within the glomerulus. The site of complex deposition may be subendothelial, subepithelial, and/or mesangial, with the associated immunologic and glomerular responses resulting in different forms of glomerulonephritis. These immune complexes may be circulating and passively trapped in mesangial or subendothelial sites; or they may form “in situ” when antibody binds to normal glomerular antigens or to soluble antigens localized within subendothelial, subepithelial, or mesangial areas. Membranoproliferative glomerulonephritis (MPGN) is probably the most common form of glomerulonephritis in dogs, accounting for 20% to 60% of cases in various studies, and is rare in cats. The term MPGN refers to the light microscopic findings of increased “membranous-like” thickening of the capillary wall with increased glomerular cellularity and is caused by the presence of immune complexes on the subendothelial aspect of the GBM (type I MPGN), with additional deposits within the mesangium or on the subepithelial aspect of the GBM (type III MPGN). Dense deposit disease (type II MPGN) is characterized by intramembranous dense deposits, is not associated with infectious diseases, and is probably uncommon in dogs. On light microscopy larger immune deposits may stain magenta with trichrome stain, making a diagnosis of MPGN more likely. However, confirmation of this diagnosis depends on demonstration of subendothelial deposits (immune complexes) via EM. In this location the immune deposits, which contain primarily IgG, are associated with proliferation of resident glomerular cells and activation of complement. Subendothelial deposits are readily accessible to circulating inflammatory cells and platelets and thus may be associated with more severe capillary wall injury. Crescents may be observed in some cases of MPGN because breaks or gaps in the damaged GBM allow the passage of fibrinogen, and later macrophages, into the urinary space. Fibrin and macrophages induce parietal epithelial cell and fibroblast proliferation, and glomerular crescents form. Glomerular diseases with significant crescent formation typically are more severe and have a rapidly progressive clinical course.

MPGN may be of unknown cause or secondary to a variety of underlying systemic and infectious diseases. In some cases of MPGN, glomeruli may be infiltrated with monocytes or neutrophils; this inflammatory infiltrate is characteristic of exudative or postinfectious glomerulonephritis. Postinfectious glomerulonephritis of humans most commonly occurs following a streptococcal infection but has also been identified with other infections (e.g., staphylococcal infection). Interestingly, this pattern of disease is usually caused by transient infections, often resolved before clinical signs of glomerular disease.

Effective treatment of the underlying infectious, inflammatory, or neoplastic disease is the cornerstone of management of patients with MPGN. Because activation of platelets appears to be involved in the pathogenesis of this disease, antiplatelet drugs also should be used. Specific data regarding the prognosis of MPGN in dogs

are lacking. In humans azotemia, severe proteinuria, systemic hypertension, and marked tubulointerstitial lesions at presentation are the most significant predictors of an unfavorable outcome.

MEMBRANOUS GLOMERULONEPHRITIS OR MEMBRANOUS NEPHROPATHY

Membranous glomerulonephritis (MGN) results from the deposition of immune complexes, most often containing IgG, on the subepithelial aspect of the GBM. Although the glomerular tufts are of normal cellularity, the capillary loops are thickened, and spikes may be evident with PASH as the basement membrane extends between the unstained immune deposits. Advanced cases may have irregular thickening and distortion of the capillary walls with occasional widening of the mesangium. The morphologic changes that occur in the glomerulus in response to immune complexes on the urinary side of the GBM are restricted because the immune complexes are separated from the vascular space and circulating inflammatory mediators. Instead the subepithelial immune deposits primarily induce complement-mediated podocyte injury with diffuse foot process effacement ultrastructurally. The podocytes also produce more basement membrane between and eventually around the immune deposits, resulting in the spikes that may be visualized with PASH staining. Confirmation of a diagnosis of MGN depends on ultrastructural demonstration of the subepithelial deposits. In animals with secondary MGN, deposits may be found elsewhere in the glomeruli.

MGN occurs in 10% to 45% of reported cases of glomerulonephritis in dogs and is the most common type of glomerulonephritis in cats. MGN appears to be more common in male dogs and cats than in females. The mean age of affected dogs is 8 years; the mean age of affected cats is only 3.6 years. Because proteinuria in affected animals may be severe, many of them present with complete or partial nephrotic syndrome.

In humans MGN is considered to be either primary (i.e., idiopathic) or secondary to another disease process; primary disease is most common. EM is used to confirm the location of the immune deposits and to characterize the stage of disease progression. Deposition of immune complexes (stage I), progressive engulfment of the complexes by the surrounding GBM (stages II and III), and eventual resolution of the deposits (stage IV) characterize the stages of MGN. These stages correlate with temporal evolution of the disease and clinical presentation in dogs, cats, and humans. In early stages proteinuria and nephritic syndrome are likely; progressive azotemia is likely during more advanced stages in cats and dogs. However, accurate staging of MGN is difficult in some animals; multiple disease stages may be present simultaneously.

In addition to identification of potentially inciting disease processes and nonspecific management, immunosuppressive therapy may be warranted in dogs or cats with persistent proteinuria caused by MGN, particularly if they appear to have idiopathic disease and are not azotemic. The clinical course of idiopathic MGN in humans varies from spontaneous complete remission in 33% to 65% of patients

to rapid progression to end-stage renal disease. The risk of progression in humans appears to correlate with the magnitude of proteinuria and renal functional impairment; patients with the highest degree of proteinuria and azotemia are more likely to have more rapid progression when compared with other patients. Although treatment of MGN in humans is controversial, some patients may respond to immunosuppressive therapy of corticosteroids combined with an alkylating agent. The approach that has proven to be most beneficial is alternating methylprednisolone and chlorambucil every other day for 6 months. Cyclosporine may be a valid option for patients not responding to corticosteroids and alkylating agents. There is evidence to suggest that humans with MGN stage I or II may be more likely to respond to immunosuppressive therapy than patients with MGN stage III or IV. Although MGN appears to be progressive in some dogs and cats, progression may be slow enough that many animals can lead relatively normal lives. In cats stages III and IV MGN may be associated with a poorer prognosis.

MESANGIOPROLIFERATIVE GLOMERULONEPHRITIS

Mesangioproliferative glomerulonephritis accounted for only 2% to 16% of glomerular lesions in dogs of two studies (MacDougall et al., 1986; Koeman et al., 1987). The mean age of affected dogs was between 7 and 9 years. Proteinuria and renal failure (mild-to-moderate, acute, or chronic) are the expected presenting signs in affected dogs. Like MPGN and MN, mesangioproliferative glomerulonephritis is an immune complex-mediated disease.

Mesangioproliferative glomerulonephritis is characterized by mesangial cell hyperplasia, defined as more than three cells per mesangial area, which is often accompanied by an increase in mesangial matrix. On EM immune complexes are present primarily within the mesangium and are mainly of the IgA class (IgA nephropathy). The diagnosis of IgA nephropathy requires a predominance of IgA positivity when examined by IFM.

IgA nephropathy is the most common type of chronic, progressive glomerulonephritis in humans and is an important cause of end-stage renal disease. As with many glomerular diseases, the severity of the tubulointerstitial lesions is a better predictor of progression than the severity of the glomerular changes. There have been several studies of canine glomerular disease that demonstrated mild-to-moderate frequency of IgA positivity via IFM, suggestive of IgA nephropathy. In one study dogs with enteric or hepatic diseases had the highest incidence of IgA deposition (Miyachi, 1992). Excessive IgA immune complex formation caused by enteric disease or decreased clearance of IgA complexes in association with liver disease have been proposed in the pathogenesis of secondary IgA nephropathy in humans. Treatment of humans with secondary IgA nephropathy is directed toward treatment of the associated systemic disease. Control of systemic hypertension is also a cornerstone of therapy. Administration of fish oil rich in ω -3 fatty acids slowed progression of renal disease in humans but did not lead to a reduction in proteinuria.

AMYLOIDOSIS

Amyloidosis is one of the most common glomerular diseases in dogs, accounting for approximately one fourth of dogs with glomerular disease; cats rarely develop glomerular amyloidosis. With the exception of the Chinese shar-pei, amyloid is deposited primarily in the glomeruli of affected dogs. Reactive amyloidosis is the most common form of amyloidosis in dogs and cats, and older animals are more commonly affected. Females appear to be affected more often than males. Beagles, English foxhounds, collies, and walker hounds may be at increased risk for amyloidosis; it may be familial in the former two breeds. Amyloid is first deposited in mesangial areas, with eventual subendothelial deposition. Because proteinuria associated with glomerular amyloidosis may be massive, many dogs present with nephrotic syndrome or pulmonary thromboembolism (caused by loss of antithrombin III). Chinese shar-pei dogs and Abyssinian cats have a familial form of reactive amyloidosis that is characterized by glomerular and medullary amyloid deposition, with medullary deposits typically predominating. In a study of shar-pei dogs only 64% had glomerular involvement, and as few as 25% to 43% of affected dogs were reported to have proteinuria (Dibartola et al., 1990). Affected shar-pei dogs and Abyssinian cats are more likely to present with azotemia rather than proteinuria since medullary interstitial amyloid deposition leads to ischemia, chronic interstitial fibrosis, papillary necrosis, and nephron loss.

In H&E stained slides glomerular amyloid appears as eosinophilic nodular deposits that expand the mesangium and glomerular capillary walls. Interstitial amyloid may be present as perivascular and peritubular deposits throughout the medulla. When stained with Congo red and evaluated by conventional light microscopy, amyloid deposits take on various shades of red, depending on the amount of amyloid and the thickness of the section. Deposits stained with Congo red and evaluated by polarizing microscopy are birefringent and have an apple-green color.

The β -pleated sheet configuration of amyloid fibrils leads to their insolubility and resistance to proteolysis, making specific treatment relatively ineffectual. Familial renal amyloidosis in shar-pei dogs and Abyssinian cats has been compared to familial Mediterranean fever in humans, which is characterized by fever of unknown origin, renal amyloidosis, and pleuritis, peritonitis, and/or synovitis. In affected humans the development of renal amyloidosis may be prevented by colchicine therapy, even in patients who continue to have recurrent febrile episodes. This has led to the recommendation that colchicine be given to shar-pei dogs with renal amyloidosis during the predeposition phase of disease, which is presumably characterized by recurrent fevers and swollen hocks. However, colchicine administration may lead to remission of proteinuria even after the appearance of amyloid deposits. There is no evidence to support that colchicine is effective once amyloidosis has resulted in renal failure. The dose of colchicine is 0.01 to 0.03 mg/kg given orally every 24 hours. Gastrointestinal upset is the primary side effect.

Dimethylsulfoxide (DMSO) has been shown to be beneficial in a limited number of dogs with renal amyloidosis, although the true benefit remains controversial (Dibartola, 1989). DMSO does not solubilize amyloid fibrils; the amount of amyloid deposited will likely remain unchanged. The antiinflammatory effects of DMSO may account for some of its beneficial effects. Reduction of interstitial fibrosis and inflammation may lead to improved renal function and reduced proteinuria. DMSO has an unpleasant odor that may lead to poor owner compliance. The recommended dosage is 90 mg/kg given orally or subcutaneously three times weekly. To reduce injection site pain DMSO should be diluted 1:4 with sterile water before administration. Nausea and anorexia are side effects in some dogs. Neither DMSO nor colchicine is effective once the plateau phase of deposition has been reached. The prognosis for dogs and cats with renal amyloidosis is generally poor.

GLOMERULOSCLEROSIS

Nonspecific glomerulosclerosis develops as an end-stage lesion in response to glomerular injury or decreased functioning renal mass. When nephron numbers are decreased, the normal response of the remaining nephrons is hypertrophy and hyperfunction. Although these adaptations have beneficial effects in increasing glomerular filtration rate, they also may cause glomerular injury, glomerulosclerosis, and in some animals a progressive decline in renal function. On light microscopy glomerulosclerosis is characterized by mesangial cell hyperplasia and mesangial expansion of portions of the glomerulus. Secondary changes such as hyalinosis and adhesions of the sclerotic portion of the tuft to Bowman's capsule are common. Animals with glomerulosclerosis secondary to chronic renal disease may be proteinuric, but their proteinuria is mild. In contrast, focal segmental glomerulosclerosis (FSGS) is a specific glomerular disease that is associated with severe proteinuria in humans. FSGS is the most common cause of the nephrotic syndrome in adult humans, but this lesion has seldom been described in nephrotic dogs and cats.

MINIMAL CHANGE DISEASE

Minimal change disease is a common cause of nephrotic syndrome in humans, but it is described uncommonly in the dog. The low prevalence in dogs may be a true finding or may be to the result of failure of detection when only light microscopy is used. Affected patients would be expected to have heavy proteinuria and a high incidence of nephrotic syndrome. In minimal change disease glomeruli are essentially normal on light microscopy, but characteristic ultrastructural lesions of diffuse foot process effacement are observed on EM. Humans with minimal change diseases tend to be highly responsive in corticosteroids, with an expected response rate of 80% to 90%.

HEREDITARY NEPHRITIS

Inherited defects in the structure of the GBM involving mutations in type IV (basement membrane) collagen

have been described in several breeds of dogs. Although the light microscopic lesions are variable and nonspecific, the ultrastructural lesions of irregular GBM splitting are unique to this disease. Therefore diagnosis of this disease depends on electron microscopic evaluation of renal tissue. There is no specific treatment for this disease, but nonspecific management by feeding a renal diet and administering angiotensin-converting enzyme inhibitors has proven beneficial.

FOLLOW-UP EVALUATION

Successful management of the dog or cat with glomerular disease requires adequate patient follow-up. The urine protein/creatinine (UP/C) ratio, urinalysis, body weight, body condition score, systemic blood pressure, and serum albumin and creatinine concentrations should be evaluated monthly when modifications in the therapeutic plan are being made. However, the patient may only need to be evaluated every 3 to 6 months if the clinical signs are stable and therapeutic changes are unlikely. Day-to-day variations in the UP/C ratios of up to 50% in dogs and 90% in cats have been described. Ideally, averaging the results of 2 to 4 UP/C ratios measured over a 3- to 5-day period provides the best estimate of proteinuria for an individual patient. Serial ratios that increase or decrease by greater than 50% in dogs and 90% in cats support a meaningful change in the magnitude of proteinuria. In dogs or cats with isosthenuric or dilute urine, a urine sample should also be submitted for bacterial culture and susceptibility testing every 6 months. Because histologic lesions do not necessarily resolve even though renal function may improve, repeat biopsies generally are not recommended.

CHAPTER 189

Measuring Glomerular Filtration Rate: Practical Use of Clearance Tests

SHERRY LYNN SANDERSON, *Athens, Georgia*

With declining renal function, urine concentrating ability is impaired when 66% of nephrons are no longer functioning, and azotemia develops when 75% of nephrons are no longer functioning. Although urine specific gravity, blood urea nitrogen (BUN), and serum creatinine are commonly used to assess renal function, these tests are affected by many variables not necessarily related to renal function.

FLAWS IN TRADITIONAL TESTS FOR RENAL FUNCTION

Nonrenal Variables Affecting Urine Concentration (Urine Specific Gravity)

Urine concentrating ability is commonly used to detect renal dysfunction; however, many variables can affect urine concentration. These include drugs, diet, concurrent disease, and even temperament.

Drugs

It is well known that certain medications can result in the production of dilute urine in dogs and cats with normal renal function. For example, corticosteroids inhibit antidiuretic hormone in dogs and produce dilute urine. Similarly, phenobarbital can also produce a low urine specific gravity in dogs with normal renal function. Furosemide, hydrochlorothiazide, and mannitol can affect urine concentration in both dogs and cats with normal renal function by producing diuresis.

Diet

Diet can influence urine concentration without impairing renal function. In particular, feeding a dog a protein-restricted diet may result in medullary washout and

production of dilute urine. Many diets prepared for renal or hepatic insufficiency, geriatric patients, and dissolution or prevention of urolithiasis are formulated to reduce protein intake. In fact, evaluating urine specific gravity and BUN levels are two methods for assessing owner compliance with the feeding of a protein-restricted diet.

Diseases

Nonrenal diseases such as diabetes mellitus, neurogenic (central) diabetes insipidus, hyperadrenocorticism, and liver failure can produce a low urine specific gravity in animals with normal renal function. The mechanism of polyuria varies, depending on the disease.

Temperament

The activities of a dog and its temperament can also influence water intake and urine concentration. These behaviors may not be considered necessarily inappropriate or suggestive of renal dysfunction.

Although it is true that urine concentrating ability is impaired when 66% of nephrons are no longer functioning, finding dilute urine does not always equate with renal disease (see chapter 184 for more information about polyuric disorders).

Nonrenal Variables Affecting BUN and Serum Creatinine

Blood Urea Nitrogen

BUN values are influenced by several factors other than glomerular filtration rate (GFR). For example, consuming a high-protein diet can increase BUN levels. Similarly, bleeding into the gastrointestinal tract can create the same effect as consuming a high-protein diet. BUN is also highly influenced by tubular resorption and is inferior to serum creatinine for estimating GFR. Therefore the main clinical

use of BUN in patients with renal disease is as an indicator of retention of harmful nitrogenous wastes in the body rather than for its value for determining renal function.

Serum Creatinine

Although serum creatinine is a better indicator of GFR than BUN, it gives only a crude estimate of GFR. Differences in the rate of creatinine production relative to diet and muscle mass may affect this value. For example, serum creatinine concentrations may decrease in dogs and cats with advanced chronic kidney disease (CKD) because of muscle wasting rather than improvement in GFR.

The analytic method used to measure serum creatinine can also influence the results. The most common method used for measuring serum creatinine is the Jaffe method. This method is not specific for creatinine, and in other species over 50 compounds found in blood can react positively by the Jaffe reaction. Nonrenal compounds contribute to as much as 50% of the value reported for serum creatinine in dogs. Most of these compounds are not excreted by the kidneys; therefore their presence in blood has nothing to do with renal function; however, these factors can falsely increase serum creatinine concentrations. In addition, great variations in serum creatinine measurements have been found among different laboratories and among different breeds of healthy dogs.

Nonlinear relationship between serum creatinine concentration and glomerular filtration rate. Although serum creatinine increases as GFR declines, this relationship is not linear. Early in CKD large decreases in GFR cause only small increases in serum creatinine; whereas in advanced stages of CKD small decreases in GFR result in large changes in serum creatinine. This occurs because the insidious loss of nephrons occurring with CKD is accompanied initially by compensatory hypertrophy of residual functional nephrons so that their single-nephron GFR may more than double. This results in enhanced excretion of nitrogenous wastes and delays onset of azotemia until more nephrons are lost. Studies with the remnant kidney model of renal failure also indicate that renal mass and nephron numbers are reduced to 10% to 15% of normal when GFR is still 25% of normal because of compensatory hypertrophy of the remaining nephrons. These findings indicate that patients are often worse off in terms of number of functional nephrons than surmised by considering GFR values. This interpretation, as well as the abundance of nonrenal influences on urine concentration, BUN, and serum creatinine levels, provides a strong argument for pursuing more sensitive methods for evaluating renal function than tests of urine concentration and azotemia currently offer.

Reciprocal of serum creatinine versus time as an indicator of glomerular filtration rate. Some investigators have suggested that plotting the reciprocal of the serum creatinine ($1/\text{SCr}$) versus time shows a linear decrease in renal function with time, providing a method for estimating GFR to follow the progression of renal disease. Others have suggested that this method often gives erroneous estimates of rates of progression because a perfect linear correlation between $1/\text{SCr}$ and GFR does not always occur.

In a recent study (Sanderson et al., 2005) the reciprocal of serum creatinine as an estimate of GFR was compared to

a plasma clearance test (iohexol clearance test) in dogs in various stages of naturally occurring CKD. Results showed that in early stages of CKD, defined as a serum creatinine less than 4 mg/dl, the reciprocal of serum creatinine was a modest indicator of GFR. However, in moderate-to-severe stages of CKD, defined as a serum creatinine of 4 mg/dl or higher, the reciprocal of serum creatinine was a poor indicator of GFR.

MORE SENSITIVE METHODS OF ASSESSING GLOMERULAR FILTRATION RATE

GFR is defined as the milliliters of plasma that are cleared of a substance over time and is expressed as milliliters per minute per kilogram of body weight. Therefore renal clearance assays are used to define GFR by determining the clearance of a plasma-borne solute from urine. The measured solute optimally should not be protein bound, should be freely filtered across the glomeruli, and should be neither secreted nor resorbed by the renal tubules. The clearance of this solute is proportional to GFR. Inulin and creatinine are well suited for this purpose.

Plasma Clearance Tests

Inulin Clearance Test

Inulin clearance is considered the gold standard for estimating GFR. However, performing an inulin clearance is labor intensive and requires continuous infusion of inulin and arduous laboratory measurements, making this technique impractical for routine use in clinical practice.

Nuclear Imaging Techniques

Nuclear imaging techniques may be an alternative method for calculating GFR. However, because of the need for specialized equipment and handling of radioactive materials, the use of this test is limited primarily to veterinary teaching hospitals and larger referral centers. Therefore this approach is largely impractical for routine use in clinical practice.

Endogenous and Exogenous Creatinine Clearance Tests

Less precise alternatives for estimating GFR include endogenous or exogenous creatinine clearance. Both endogenous and exogenous creatinine clearance tests require that urine be collected during precisely defined time intervals. Accurate urine collections require intermittent catheterization of the urinary bladder, procedures that are labor intensive and stressful for the patient.

Endogenous creatinine clearance test. The endogenous creatinine clearance test is not suitable for detecting slight changes in renal function because noncreatinine chromagens constitute a large percentage of plasma chromagens and lead to underestimation of renal function. Another criticism of the endogenous creatinine clearance test is the considerable variability inherent in this measurement.

Exogenous creatinine clearance test. In the exogenous creatinine clearance test a larger dose of creatinine is administered to minimize the effects of noncreatinine

chromagens. However, creatinine clearance may not accurately estimate GFR in heavily proteinuric patients because, as glomerular disease worsens, there is progressive hypersecretion of creatinine by remnant renal tubules (Shemesh, 1985).

Iohexol Clearance as an Alternative Test of Glomerular Filtration Rate

Until recently diagnosing early (preazotemic) renal disease in dogs and cats was limited primarily to renal clearance tests such as inulin or creatinine clearance. The inability to readily assess renal function in a practical way often posed a dilemma for clinicians with patients in which the only finding was a low urine specific gravity. As a result, detection of early (preazotemic) renal disease was often missed. In addition, assessing renal function in patients with azotemic renal failure also has inherent limitations, as outlined previously.

Iohexol Clearance Test

The iohexol clearance test can be used in clinical practice to estimate GFR in dogs or cats. It is easy to perform and does not require specialized equipment or collection of urine. The relative ease in performing plasma or serum clearance procedures compared to urinary clearance procedure makes this test especially attractive.

Iohexol (Omnipaque) is a low-osmolar, nonionic, iodinated radiographic contrast medium used for radiographic procedures in both human and veterinary medicine. By measuring the plasma or serum disappearance of iodine following a single intravenous dose of iohexol, GFR can be estimated (see Table within Box 189-1 for complete protocol for performing iohexol clearance).

Iohexol clearance was compared to urinary clearance of exogenous creatinine in 10 dogs with normal renal function and in 12 dogs with surgically reduced renal mass (Finco, Braselton, and Cooper, 2001). Plasma was analyzed for iohexol by three assay methods: chemical, high-performance liquid chromatography (HPLC), and inductively coupled plasma emission spectroscopy (ICP). Results showed significant correlation between iohexol clearance and urinary clearance of exogenous creatinine using all three of the assay methods (chemical: $R^2 = 0.90$; HPLC: $R^2 = 0.96$; and ICP: $R^2 = 0.96$). The investigators concluded that iohexol clearance is a reliable marker of GFR in dogs.

Iohexol clearance has also been evaluated in cats. In one study (Miyamoto, 2001a) four renal-intact and six partially nephrectomized adult cats were evaluated. Iohexol clearance results were compared to (exogenous) urinary clearance of creatinine. Correlation between iohexol clearance and (exogenous) urinary clearance of creatinine for all cats was high ($R = 0.951$). In a second study by the same author (Miyamoto, 2001b) 52 cats presenting for a variety of problems were studied. Results indicated that the iohexol clearance test was a much more sensitive indicator of renal dysfunction than BUN and plasma creatinine. Therefore, as in dogs, iohexol clearance in cats provides a reliable and sensitive estimate of GFR.

Indications for Iohexol Clearance Tests

The following is a list of potential indications for performing an iohexol clearance test:

1. Assessing renal function in nonazotemic patients in which the only clinical signs are polyuria and polydipsia. Although administering iohexol to dogs and cats has the potential to be associated with adverse reactions, the risks of performing this test are far fewer than the risks of performing an inappropriately conducted water deprivation test (see Chapter 184). The iohexol clearance test often yields more useful results than the water deprivation test. The author recommends that an iohexol clearance test be performed in all patients before considering a water deprivation test.
2. Identifying occult renal dysfunction before procedures or therapy that may be detrimental to renal function.
3. Optimizing dosing schedules for drugs eliminated by glomerular filtration in patients with renal dysfunction, especially in patients receiving nephrotoxic drugs.
4. Screening nonazotemic patients with a familial history of renal dysfunction with the goal of identifying affected individuals and initiating appropriate therapy before the onset of azotemia.
5. Assessing discrepancies between serum creatinine and BUN. Since nonrenal parameters can affect both of these tests, it is often difficult to determine which one of the tests is responsible when a disparity exists.
6. Accurately assessing severity of renal dysfunction in patients with CKD and monitoring changes in renal function after initiating therapy.

Potential Complications and Adverse Effects of the Iohexol Clearance Test

Although uncommon, adverse reactions to iohexol can occur. Similar to other radiographic contrast media, potential adverse effects include anaphylaxis, cardiac arrhythmias and hypotension, gastrointestinal symptoms (nausea and vomiting), and acute renal failure.

Anaphylaxis. If the clinician is concerned that a patient may be at risk for developing an anaphylactic reaction to intravenous iohexol, the patient can be premedicated with diphenhydramine (0.5 mg/kg intramuscularly). In an ongoing study of CKD, one dog (a 10-year-old, male castrated Shetland sheepdog) had a history of having a mild adverse reaction (vomited) to a radiographic contrast agent administered for an excretory urogram. Multiple iohexol clearance tests were performed safely in this dog after pretreatment with diphenhydramine. Although the potential for anaphylactic reactions exists and clients need to be counseled accordingly, the incidence appears infrequent.

Cardiac arrhythmias and hypotension. In humans cardiac arrhythmias and hypotension are rare (0.7% to 2%) complications associated with intravenous administration of iohexol. It is unknown how often this occurs in dogs and cats. Nonetheless it would be prudent to keep this in mind in patients with preexisting heart disease.

Gastrointestinal complications. Nausea and vomiting are also infrequent complications (0.7% to 2%)

Box 189-1

Protocol for Estimation of Glomerular Filtration Rate In Dogs and Cats by Serum Iohexol Clearance

1. Patient should be well hydrated and fasted for 12 hours before the iohexol clearance study (do not restrict water intake).
2. Record an accurate body weight in kilograms.
3. Place an intravenous catheter and flush with sterile saline to ensure catheter patency before the administration of iohexol.
4. If concerned about an adverse reaction to iohexol, pretreat the patient with diphenhydramine.
5. Administer a single dose of iohexol (150 to 300 mg/kg) as a rapid intravenous bolus and record time administered to the nearest minute. Iohexol is relatively expensive, especially when used in a large dog. Severity of azotemia may impact the dose of iohexol used:
 - A. With mild azotemia it is best to choose a 300-mg/kg intravenous dose of iohexol to ensure that sufficient iohexol will remain in the blood to be detected by the assays used to measure it.
 - B. With moderate-to-severe azotemia, it is acceptable to use a 300-mg/kg intravenous dose of iohexol. However, because renal clearance of iohexol is impaired, a lower dose (150 mg/kg intravenously) of iohexol often can be used.
6. After administering the intravenous dose of iohexol, blood is collected in a clot tube at 2, 3, and 4 hours after iohexol injection. *It is VERY important to record the times samples were collected to the nearest minute.* See following table.
7. Allow the blood sample to clot before centrifuging, and transfer serum (0.4 ml or more) into a plastic appropriately labeled vial. Serum samples may be refrigerated or frozen.
8. Ship chilled or frozen serum samples to the analytical laboratory in an insulated container. Be certain to include the exact dose of iohexol administered (milligrams of iodine per kilogram of body weight), the exact time of iohexol administration, and the exact time samples were collected (see following table).
9. One laboratory that is equipped for analysis of iohexol clearance is the University Animal Diagnostic Laboratory, at Michigan State University (B629 West Fee Hall, East Lansing, MI 48824; phone: 517-355-0281).
10. GFR will be reported in ml/min/kg body weight.

Example of a Table Used For Iohexol Clearance

Animal Name and ID	Body Wt (kg)	Test Date	Iohexol Dose	Time of Administration	Sample Times (AM OR PM)		
					2 hr	3 hr	4 hr

From Kruger et al., 1998.

associated with iohexol administration in humans. Although the potential for similar complications exists in dogs and cats, gastrointestinal effects appear to be very rare.

Acute renal failure. Radiographic contrast agents markedly aggravate outer medullary hypoxia and generate cytotoxic reactive oxygen species (Heyman, Reichman, and Brezis, 1999). The pathophysiology of contrast-induced nephropathy results from enhanced medullary metabolic activity and oxygen consumption as a result of osmotic diuresis and increased salt delivery to the distal nephron. The major risk factors for radiocontrast nephropathy in humans are (1) administering high doses of contrast media; (2) dehydration; (3) decreased effective arterial volume secondary to congestive heart failure, cirrhosis, or nephrotic syndrome; (4) factors favoring prerenal failure problems such as administration of non-steroidal antiinflammatory drugs or angiotensin-converting enzyme inhibitors; and (5) preexisting renal failure (Esnault, 2002).

The majority of complications associated with administering radiographic contrast material occur when *high-osmolality, nonionic radiocontrast media* is used. Since the introduction of *low-osmolality, nonionic radiocontrast media* (including iohexol), acute adverse reactions to radiographic contrast media are uncommon. I have performed more than 50 iohexol clearance tests in dogs with various stages

of naturally occurring CKD and have not encountered any known adverse reactions to iohexol in these patients.

Evidence-Based Management of Chronic Kidney Disease

DAVID J. POLZIN, *St. Paul, Minnesota*
CARL A. OSBORNE, *St. Paul, Minnesota*
SHERI ROSS, *St. Paul, Minnesota*

OVERVIEW OF EVIDENCE-BASED MEDICINE

The purpose of evidence-based medicine is to facilitate application of current standards of medical care based on best available evidence of the benefits, limits, and risks of treatment recommendations. Several factors should be considered when making a recommendation for treatment, including: (1) the established goal of the treatment, (2) whether there is reasonable assurance of safety and effectiveness for the treatment, (3) the magnitude of benefit expected to accrue from the proposed therapy, and (4) the likely impact of owner compliance and satisfaction with the treatment. Ideally therapy should both prolong and enhance the pet's quality of life, be free of significant adverse effects or risks, place manageable demands on the owner's time and financial resources, and not disrupt the relationship between the owner and pet. When the therapeutic plan fails to achieve these goals, poor compliance, treatment failure, or euthanasia may result because the needs of the pet and owner have not been met. Therapeutic success may be facilitated by using best available evidence to prioritize treatment recommendations and educate pet owners as to what they can reasonably expect from treatment.

Whenever possible, treatment recommendations should be based on results of rigorous, controlled scientific studies. Of course, not all recommendations can be based on such studies. Nonetheless, it is important to recognize the inherent limitations of recommendations based on less secure forms of evidence. Unfortunately many therapies recommended for dogs and cats with chronic kidney disease (CKD) have never been examined in an appropriate and systematic fashion in clinical patients. Often treatments are recommended on the basis of less convincing forms of evidence such as clinical experience, expert opinion, pathophysiologic rationale, studies performed in other species, or studies in dogs or cats with induced disease. Evidence from the recalled experiences of clinicians and other experts tends to overestimate the efficacy of a therapy or other interventions.

One suggested method of accommodating concerns regarding these limitations in evidence is to assign a score defining the strength and quality of the recommendation. We have chosen to use a four-point system of grading for this purpose. Grade 1 evidence, the highest-quality evidence, is that obtained from at least one properly random-

ized controlled clinical trial (RCCT) or a meta-analysis of multiple RCCTs. Such studies yield an estimate of effectiveness that reflects the likely effect of the treatment when applied to patients in a clinical setting. Grade 1 evidence provides strong support for a recommendation. Grade 2 evidence is data collected from studies performed using acceptable laboratory models or simulations in the target species. These studies yield an estimate of efficacy (rather than effectiveness) that reflects the effect of the treatment in an idealized setting that may or may not represent the true conditions under which the treatment is typically applied clinically. Grade 3 evidence is data obtained from at least one well-designed clinical trial without randomization, from cohort or case-controlled analytic studies, or from uncontrolled studies in which dramatic results are obtained. Grades 2 and 3 evidence provides intermediate or moderate support for a recommendation. Grade 4 evidence includes recommendations based on the opinions of respected authorities derived from clinical experience, descriptive studies, studies in other species (e.g., humans and rodent models), pathophysiologic justification, and reports of expert committees. Grade 4 evidence provides weak support for a recommendation.

An additional element to consider when examining evidence supporting or refuting a therapeutic claim is whether the evidence is clinically relevant. Treatments are indicated when they provide important clinical benefits. Unfortunately studies often focus on outcomes that may or may not have any clinical relevance to pets and their owners. For example, a study linking calcitriol therapy to correcting hyperparathyroidism does not necessarily provide sufficient reason for recommending such therapy in terms of major clinical outcomes of survival and quality of life. Parathyroid hormone activities or other physiologic or laboratory measurements are often used as "substitute" or "surrogate" end points in studies because typically they are obtained more easily than more important clinical outcomes. Such results only provide a pathophysiologic rationale for applying the treatment to patients (i.e., grade 4 evidence). It is of primary importance to provide evidence that the treatment influences major outcomes that are important to pets and their owner. These include increased activity or appetite, decreased vomiting, decreased incidence of uremic crises requiring urgent hospitalization, and prolonged good-quality life span.

In this chapter we provide guidelines for managing dogs and cats with CKD and the strength of evidence

supporting the recommended guidelines. The strength of evidence supporting the guidelines can be used to assess the relative priorities of various therapies. It is appropriate that the owner and veterinarian commit substantial effort toward treatment recommendations supported by strong evidence as compared to efforts expended on carrying out treatments supported only by weak evidence.

LINKAGE BETWEEN STAGE OF CHRONIC KIDNEY DISEASE AND TREATMENT RECOMMENDATIONS

Classification of CKD according to guidelines developed by the International Renal Interest Society is an important advance in our approach to managing CKD in dogs and cats (see Chapter 192). According to this classification system, treatment recommendations can be rationally

linked to the magnitude of reduction in kidney function and the presence or absence of proteinuria and hypertension. These three core characteristics of CKD patients (the magnitude of renal dysfunction, proteinuria, and hypertension) are related to the risk for development of clinical complications and additional loss of kidney function and therefore serve as a logical basis for evaluating and justifying therapeutic intervention. Indications for treatment recommendations are provided using this staging system (Table 190-1).

CONSERVATIVE MANAGEMENT OF CHRONIC KIDNEY DISEASE: THERAPEUTIC OPTIONS

Conservative medical management of CKD can be synthesized into the following four general treatment goals:

Table 190-1

Evidence-based Management of Chronic Kidney Disease in Dogs and Cats

Recommendation	Indication	Treatment Options	Goal of Treatment	Evidence Supporting Recommendation
Feed a renal diet	D: CKD stages III, IV C: CKD stages II*, III, IV	Manufactured diets Homemade diets	Ameliorate risk of developing uremia or premature death Slow progression of CKD Maintain or improve nutrition Control phosphorus intake	Grade 1 D & C: RCCT
Ameliorate GI signs[†]	CKD stages III, IV with GI signs attributable to CKD present	H ₂ blockers [‡] Sucralfate Antiemetics	Ameliorate and/or prevent GI signs associated with uremia, including anorexia, nausea, vomiting, GI ulceration, and blood loss	Grade 4 Opinion and pathophysiologic justification
Optimize nutrition	CKD stages III, IV with inadequate oral calorie intake	Esophagostomy tube Gastrostomy tube	Provide adequate calorie intake Achieve and maintain a body condition score of 5/9	Grade 4 Opinion and descriptive studies
Supplement ω-3 PUFAs	CKD stages II-IV	Supplements containing ω -3 PUFAs	To slow progression of CKD	D: Grade 2 Induced model of CKD C: Grade 4 Pathophysiologic justification; extrapolation from other species; retrospective study in cats
Correct hyperphosphatemia	CKD stages II, III, IV	Reduced phosphorus diet Intestinal phosphorus binders	Slow progression of CKD CKD Stages 2 and 3: Serum phosphorus of ≤ 4.5 or ≤ 5 mg/dl or lower, respectively CKD Stage 4: Serum phosphorus of 6 mg/dl or lower	D: Grade 2 Induced model of CKD C: Grade 4 Pathophysiologic justification; extrapolation from other species; inference from clinical trials in cats
Correct hypokalemia	CKD stages III, IV with serum potassium concentration < 3.5 mEq/L	Potassium supplementation (e.g., potassium gluconate or citrate)	Maintain serum potassium concentration 4.0 to 5.4 mEq/L Stabilize kidney function (?) Correct hypokalemic polymyopathy	Grade 4 Opinion and pathophysiologic justification
Correct metabolic acidosis	CKD stages I-IV	Sodium bicarbonate Potassium citrate Renal diet	Maintain serum bicarbonate concentration 18 to 24 mEq/L Minimize protein catabolism	Grade 4 Opinion and pathophysiologic justification

Table 190-1—Cont'd

Evidence-based Management of Chronic Kidney Disease in Dogs and Cats

Recommendation	Indication	Treatment Options	Goal of Treatment	Evidence Supporting Recommendation
Maintain hydration	CKD stages III,IV with evidence of chronic or recurrent dehydration	Long-term subcutaneous fluid therapy Provide water through feeding tube	Correct clinical signs associated with dehydration Reduce magnitude of azotemia Stabilize or improve kidney function	Grade 4 Opinion and pathophysiologic justification
Ameliorate proteinuria	CKD stages I-IV Stage I UP/C ≥ 2.0 D: Stages II-IV UP/C >0.5 C: Stages II-V UP/C >0.4	Angiotensin-converting enzyme inhibitors Angiotensin receptor blockers	Reduce proteinuria (by at least one half, or, ideally, to UPC <1.0) Slow progression of CKD Reduce risk of premature death	Grade 1 D and C: For reducing proteinuria (RCCT) Grade 4 For slowing progression of CKD in dogs and in cats (pathophysiologic justification; findings in humans)
Ameliorate hypertension	CKD stages II-IV with blood pressures above 160/100	Angiotensin-converting enzyme inhibitors Amlodipine Other antihypertensives Limit sodium intake (?)	Reduce blood pressure below 160/100 Reduce risk of hypertension-induced injury to eyes, kidneys, CNS, and cardiovascular system	C: Grade 2 Evidence of lowered risk of hypertensive retinopathy (RCCT using amlodipine) D: Grade 4 Opinion and pathophysiologic justification
Correct anemia	CKD stages III,IV	Minimize blood loss rHuEPO or darbepoetin	D: Maintain hematocrit between 38 and 48 C: Maintain packed cell volume between 30 and 40	Grade 3 rHuEPO: Nonrandomized trial in dogs and cats Grade 4 Darbepoetin: Opinion and pathophysiologic justification
Administer calcitriol	CKD stages III,IV	Oral calcitriol	Slow progression of CKD Reduce risk of premature death Minimize renal secondary hyperparathyroidism	D: Grade 1 RCCT C: Grade 4 RCCT does not support; pathophysiologic justification; extrapolation from other species

C, Cats; CKD, chronic kidney disease; CNS, central nervous system; D, dogs; GI, gastrointestinal; PUFA, polyunsaturated fatty acid; rHuEPO, recombinant human erythropoietin; RCCT, randomized controlled clinical trial; UPC, urine protein/creatinine.

*Evidence in cats supports intervention for cats with serum creatinine 2 mg/dl (mid-stage 2).

[†]GI signs: gastrointestinal signs such as anorexia, nausea, vomiting, and GI bleeding.

[‡]Ranitidine, famotidine.

(1) to provide adequate and appropriate nutritional support; (2) to correct deficits and excesses in fluids, acid-base, and electrolytes (i.e., sustain a normal internal milieu); (3) to ameliorate clinical signs of CKD; and (4) to provide renoprotective therapy to slow progression of CKD. The guidelines provided in this chapter provide a framework for achieving these treatment goals.

Provide Adequate and Appropriate Nutritional Support

Guideline 1: Recommend Feeding a Renal Diet

There is strong evidence (grade 1) supporting a recommendation to feed a renal diet to dogs and cats with serum creatinine concentrations in excess of 2 mg/dl (CKD stages III and IV in dogs and mid-II through IV in

cats). Benefits shown to accrue from dietary therapy in dogs and cats include preventing or delaying the onset of uremia and premature death from complications of CKD. At least in dogs, these benefits have been shown to accrue from slowing progression of CKD. In addition, these diets have been shown to maintain or improve nutrition. Evidence supporting the recommendation to feed renal diets includes findings of randomized controlled clinical trials in dogs and cats with spontaneous CKD (Jacob, Polzin, and Osborne, 2002; Polzin, Osborne, and Ross, 2005; Ross et al., 2006). The canine RCCT indicated that diet therapy reduced the risks of uremic crisis and renal death by 72% and 69%, respectively, over the 2 years of study, with a median survival time of 594 days in dogs fed the renal diet compared to 188 days in dogs fed a maintenance-type diet. In the

feline RCCT there was sufficient survival in both diet groups after 2 years of study that median survival times could not be compared (Ross et al., 2006). However, in a nonrandomized clinical trial performed in cats with naturally occurring CKD, the median survival time for cats consuming the renal diet was 633 days compared to 264 days for cats that did not switch to a renal product (Elliot et al., 2000). Patient and owner acceptance of the diets used in these studies was excellent, perhaps in large part because of gradual introduction of the diets over several weeks.

Guideline 2: Ensure Adequate Nutrition

Owners often consider food consumption to be a premier indicator of their pet's quality of life, and they are happy when their pet shows any interest in food. However, it is inappropriate to accept the pet's consumption of "some" food as a goal of therapy. Malnutrition is a major cause of morbidity and mortality in dogs and cats with CKD stages 3 and 4. Ideally patients should consume enough calories from an appropriate diet to maintain a body condition score of 4 to 5/9. Increased efforts are indicated to ensure sufficient calorie intake for patients with body condition scores of 3/9 or lower or when patients fail to consume adequate calories to maintain a stable, appropriate body weight. In addition to inattention to adequate nutrition, some factors that may contribute to malnutrition in dogs and cats with CKD include consumption of inappropriate diets and metabolic factors related to uremia (especially uremic gastrointestinal signs and metabolic acidosis). Since inappropriate diets can exacerbate clinical signs of uremia and/or promote progression of CKD, cats and dogs with CKD should be fed a renal diet. Failure to adequately address uremic gastritis, uremic stomatitis, and dental health can promote anorexia. Metabolic acidosis can promote protein catabolism and malnutrition.

It is appropriate to consider placing a feeding tube when patients fail to spontaneously consume adequate food. Feeding via gastrostomy or esophagostomy tube is a simple and effective way to provide an adequate intake of calories and water. In addition, feeding tubes simplify drug administration (see also Chapter 196). Based on this line of reasoning, use of feeding tubes has been recommended for CKD patients. However, there is only weak evidence to support use of feeding tubes to meet caloric needs of dogs and cats with CKD (grade 4).

Guideline 3: Provide Omega-3 Polyunsaturated Fatty Acids

Omega-3 (ω -3) Polyunsaturated fatty acid (PUFA) supplementation should be considered for dogs and cats with CKD stages II through IV and stage I patients with proteinuria. However, the ideal quantity of ω -3 PUFA supplementation is not known, nor is it clear whether it is the quantity of ω -3 PUFAs or the ratio of ω -6: ω -3 PUFAs that is of primary importance. Most renal diets are supplemented with ω -3 PUFAs or have an enhanced ω -6: ω -3 PUFA ratio.

Potential benefits of ω -3 PUFAs include stabilization or improvement in renal function; preservation of renal structure; and reductions in proteinuria, intraglomerular hypertension, systemic hypertension, and hyperlip-

idemia. These benefits are thought to accrue, at least in part, as a result of antiinflammatory, antithrombotic, and antioxidant effects associated with modification of prostanoïd, thromboxane, and leukotriene production.

There is moderate evidence (grade 2) to support the recommendation to provide ω -3 PUFAs in dogs with CKD but only weak evidence (grade 4) to support providing it in cats with CKD. Evidence of therapeutic efficacy of ω -3 PUFA supplementation has been demonstrated in induced CKD in dogs, in which it was associated with improved renal function, renal structure, and survival (Brown, 1998). In cats evidence is limited to results of a retrospective study of cats with spontaneous CKD in which those surviving the longest were receiving the diet with the highest ω -3 PUFA content (Plantinga et al., 2005).

Correct Deficits and Excesses in Fluids, Acid Base, and Electrolytes

Guideline 4: Maintain Serum Phosphorus Concentration Below Target

Intervention to manage serum phosphorus concentration is indicated for dogs and cats with CKD stages II to IV when serum phosphorus concentration rises above the therapeutic target concentration. Ideally serum phosphorus concentration should be maintained below 4.5 mg/dl in stage II, below 5 mg/dl in stage III, and below 6 mg/dl in stage IV. When serum phosphorus concentration exceeds the target concentration, dietary phosphorus restriction should be initiated using a renal diet. In most dogs and cats with CKD stages II and III, dietary phosphorus restriction alone maintains the desired serum phosphorus concentration. However, in some CKD stage III patients and most CKD stage IV patients, addition of an intestinal phosphate binding agent is necessary to reduce serum phosphorus concentration below the target concentration. The most commonly used intestinal phosphate binding agents in dogs and cats contain aluminum as hydroxide, oxide, or carbonate salts. Because of concern about aluminum toxicity in humans, aluminum-containing binding agents are becoming more difficult to obtain. Although there have been isolated reports of hematologic, skeletal, and neurologic complications of aluminum toxicity in CKD dogs, aluminum-containing binding agents usually appear to be well tolerated and safe in dogs and cats. Alternative drugs that do not contain aluminum include calcium carbonate, calcium acetate, sevelamer hydrochloride, or lanthanum carbonate. Experience with these drugs in dogs and cats is limited, but hypercalcemia may be a problem with the calcium-based products, particularly when administered with calcitriol.

There is moderate (grade 2) evidence to support recommending a phosphorous-restricted diet for dogs with CKD (Brown et al., 1991); however, the evidence in cats with CKD is weak (grade 4). Although strong evidence supports feeding a renal diet in CKD in both species, the specific effect of phosphorus intake on clinical outcome has only been documented in dogs with induced CKD in which dietary phosphorus restriction was shown to slow progression of CKD and improve survival. Similar studies have not been reported in cats, although phosphorus

restriction has been shown to reduce renal mineralization in cats with induced CKD. There is only weak (grade 4) evidence supporting the specific targets for serum phosphorus concentration given in this chapter.

There is only weak evidence (grade 4) supporting a recommendation to use intestinal phosphate binding agents to achieve target blood phosphorus concentrations in dogs with CKD. To date there have been no studies reporting the effect of phosphate binders on clinical outcomes in dogs and cats with CKD, although there are descriptive studies suggesting that intestinal phosphate binders are effective in reducing serum phosphorus concentrations.

Guideline 5: Maintain Serum Potassium Concentration Within the Target Range

Intervention to manage serum potassium concentration is indicated for dogs and cats with CKD stages I through IV when serum potassium concentration decreases below or rises above the target range of 3.5 to 5.5 mEq/L. The goal of therapy is to bring serum potassium concentration above 4 mg/dl. Hypokalemia is primarily of concern in cats with CKD or cats and dogs with renal tubular disorders such as Fanconi syndrome. Hypokalemia in cats with CKD is presumed to result from inadequate intake and enhanced urinary losses. It has been suggested that increased urinary losses may result in part from enhanced activation of the renin-angiotensin-aldosterone system in response to low-sodium diets. Clinical effects of hypokalemia may include varying degrees of skeletal, smooth, and cardiac muscle weakness and impairment in kidney function. Treatment of hypokalemia usually involves oral or parenteral administration of potassium salts and enhancing food intake. Potassium gluconate and potassium citrate are the preferred salts for oral administration; potassium chloride is used parenterally.

Hyperkalemia is primarily of concern in CKD stage IV when the renal excretory capacity for potassium excretion is no longer able to excrete the daily potassium load provided by the diet. However, it may also occur in association with therapeutic blockade of the renin-angiotensin system and with hyporeninemic hypoaldosteronism. The primary clinical consequence of hyperkalemia is cardiotoxicity. Treatment usually involves reducing the potassium content of the diet. Hyperkalemia resulting from blockade of the renin-angiotensin system may require reduction in drug dosage should the risk of significant cardiotoxicity develop.

There is only weak evidence (grade 4) supporting a recommendation to provide potassium supplementation to stabilize or improve renal function in cats with CKD. A randomized controlled clinical trial examining the effect of oral potassium supplementation on total body potassium and kidney function failed to yield conclusive findings (Theisen et al., 1997). Recommendations for managing hyperkalemia are based on descriptive studies and pathophysiologic justification (evidence grade 4).

Guideline 6: Correct Metabolic Acidosis

Intervention to correct metabolic acidosis is indicated for dogs and cats with CKD stages I to IV when blood bicarbonate concentration drops below the therapeutic target

concentration of 18 mEq/L (19 mEq/L for total carbon dioxide concentration). Metabolic acidosis in CKD results primarily from impaired renal ammoniogenesis, although impaired excretion of titratable acid and impaired resorption of bicarbonate may contribute as well. Metabolic acidosis also occurs in patients with renal tubular acidosis (RTA) because of either impaired bicarbonate resorption (proximal RTA) or impaired urine acidification (distal RTA). Clinical effects of metabolic acidosis may include progressive renal injury and increased protein catabolism with loss of lean tissue. Treatment of metabolic acidosis involves administration of an alkalinizing salt, usually sodium bicarbonate or potassium citrate, in a sufficient amount to increase blood bicarbonate concentration into the normal range. However, there is only weak evidence (grade 4) to support the recommendation to maintain blood bicarbonate concentration above the target concentration. The recommendation is based on extrapolation from studies in other species and pathophysiologic justification.

Guideline 7: Maintain Hydration

Intervention to correct and prevent dehydration is indicated for dogs and cats with CKD stages II through IV with clinical evidence of dehydration. Maintenance of hydration in CKD depends on adequate compensatory polydipsia. Cats with CKD appear to be particularly susceptible to chronic dehydration, perhaps because the magnitude of compensatory polydipsia is inadequate. However, lack of adequate access to good-quality drinking water, certain environmental conditions, and intercurrent illnesses that limit fluid intake or promote fluid losses (e.g., pyrexia, vomiting, or diarrhea) may lead to dehydration. The clinical consequences of chronic dehydration include decreased appetite, lethargy, weakness, constipation, prerenal azotemia, and predisposition to acute kidney injury. Additional loss of kidney function from acute kidney injury is a potentially important cause for progression of CKD. The goal of therapy is to correct and prevent dehydration and its clinical effects.

Acute dehydration should be corrected quickly to minimize the risk of additional renal injury. Ideally fluid restoration should be provided promptly via intravenous administration of a balanced electrolyte solution. However, in mild dehydration and when economic considerations prohibit an intravenous approach, oral or subcutaneous therapy may be considered. The key goal of therapy with acute dehydration is rapid restoration of adequate renal perfusion to limit the risk of additional renal injury.

In patients with chronic or recurrent evidence of dehydration and in which conditions responsible for dehydration cannot be identified and corrected, long-term subcutaneous fluid therapy may be considered. Typically a balanced electrolyte solution (e.g., lactated Ringer's solution) is administered subcutaneously every 1, 2, or 3 days as needed. The volume administered depends on the size of the patient, with a typical cat receiving about 75 to 100 ml per dose. If the clinical response of the patient is less than desired, the dose can be increased cautiously. However, it is important to recognize that, although the patient is polyuric, it is possible to induce fluid overload

with excessive administration of subcutaneous fluids. In addition, sodium-containing fluids used for subcutaneous therapy do not provide electrolyte-free water and may promote systemic hypertension, hyponatremia, or circulatory overload in patients with compromised cardiac function. A more physiologically appropriate approach to maintaining hydration is to place a feeding tube and provide water via the feeding tube. This approach may also be easier for clients that find it difficult to administer fluids subcutaneously.

There is only weak evidence (grade 4) supporting a recommendation to provide long-term subcutaneous fluid therapy to patients with CKD. The recommendation is based on descriptive studies and pathophysiologic justification.

Ameliorate Clinical Effects of Chronic Kidney Disease

Guideline 8: Correct Clinically Apparent Anemia

Treatment of anemia of CKD is indicated in dogs and cats with CKD stages III and IV when the hematocrit declines below acceptable levels and the patient has clinical signs attributable to anemia. Clinical signs that may be attributable to anemia in patients with CKD include impaired appetite, lethargy, weakness, and decreased social interaction. The primary cause for anemia of CKD is impaired erythropoietin (EPO) production caused by loss of functioning kidney tissue. Other factors that may exacerbate anemia include blood loss, iron deficiency, poor nutrition, hyperparathyroidism, and infections.

The most effective means of correcting anemia of CKD is administration of EPO, either as recombinant human EPO (rHuEPO; Epogen, Procrit) or darbepoetin (Aranesp). There is moderate evidence (grade 3) to support a recommendation to use rHuEPO to correct the anemia of CKD. An uncontrolled clinical trial confirmed that rHuEPO was effective in increasing hematocrit values in dogs and cats with CKD (Cowgill et al., 1998). The increase in hematocrit appeared to be associated with improved appetites and other clinical signs attributable to anemia in cats. However, anti-EPO antibodies developed in some dogs and cats, leading to progressive nonregenerative anemia unresponsive to further rHuEPO administration. Patients treated with rHuEPO should be monitored closely for recurrence of anemia, which may herald the onset of anti-EPO antibodies. Treatment should be terminated if antibody-associated anemia is suspected to minimize antibody production. Darbepoetin may be less likely to induce anti-EPO antibodies. However, experience with darbepoetin is limited, and there is only weak evidence (grade 4) to support its use in dogs and cats with anemia of CKD. See Chapter 198 for an extensive discussion of this topic.

Guideline 9: Ameliorate Gastrointestinal Signs of Chronic Kidney Disease

Dogs and cats in CKD stages III and IV may have gastrointestinal complications of CKD, including reduced food intake, nausea, vomiting, uremic stomatitis and halitosis, gastrointestinal hemorrhage, diarrhea, and hemorrhagic

colitis. In addition, gastrointestinal hemorrhage may lead to iron deficiency anemia. Treatment for these gastrointestinal signs largely focuses on ameliorating uremic gastritis by: (1) limiting gastric acidity using H_2 blockers (ranitidine, famotidine); (2) suppressing nausea and vomiting using antiemetics (metoclopramide, 5-HT₃ receptor antagonists such as ondansetron HCl or dolasetron mesylate, the newer NK₁ antagonist maropitant, or low doses of the phenothiazine tranquilizer prochlorperazine); and (3) providing mucosal protection using sucralfate. Of these treatments, H_2 blockers are by far the most commonly used, and few adverse effects have been attributed to their use in CKD patients. Antiemetics typically are added when anorexia, nausea, or vomiting persists despite the use of an H_2 blocker. Sucralfate is added when gastrointestinal ulcerations and hemorrhage are suspected. Unfortunately there is only weak evidence to support a recommendation for any of the drugs described here in dogs and cats with CKD. Evidence of therapeutic effectiveness is limited to pathophysiologic justification and clinical experience (grade 4).

Provide Renoprotective Therapy to Slow Progression of Chronic Kidney Disease

Guideline 10: Reduce the Magnitude of Proteinuria

It is appropriate to initiate efforts toward reducing glomerular proteinuria in dogs and cats with CKD stages I through IV. Therapeutic intervention is indicated when the urine protein/creatinine (UP/C) ratio exceeds 2.0 in dogs and cats with CKD stage I and the UP/C ratio exceeds 0.5 in dogs and 0.4 in cats with CKD stages II through IV. Proteinuria has been shown to adversely affect outcomes in humans, dogs, and cats with CKD (grade 3 evidence). In dogs the risk of an adverse event (uremic crisis or death) was found to increase by 1.5-fold for every 1-unit increase increment in the UP/C ratio above 1.0. These adverse effects associated with proteinuria likely occur because proteinuria itself appears to injure the renal tubules, thereby promoting progression of CKD. It is now well established in humans that therapeutically reducing proteinuria by suppressing the renin-angiotensin-aldosterone system ameliorates proteinuria and slows progression of renal injury. (An alternative explanation is that proteinuria is a marker for or a part of another injurious process.) The evidence in dogs and cats is similar although somewhat less compelling. In an RCCT in dogs with glomerulopathies, treatment with the angiotensin-converting enzyme (ACE)-inhibitor enalapril significantly reduced proteinuria, but the duration of the study was too brief to adequately assess renoprotective value of the therapy. However, in a study examining the effects of enalapril in Samoyed dogs with hereditary nephritis, treated dogs survived 1.36-fold longer than untreated dogs. In cats with UP/C ratio values greater than 1.0, treatment with benazepril was associated with longer survival times. However, in cats with UP/C ratio values less than 1.0, the data were equivocal. This latter finding is consistent with observations in humans suggesting that the magnitude of benefit accruing from ACE inhibitors is proportional to the magnitude of reduction in proteinuria.

There is weak evidence (grade 4) that ACE inhibitor therapy slows progression of kidney disease or prolongs survival in dogs and cats (Grauer et al., 2000; Lees et al., 2005).

Guideline 11: Minimize Systemic Hypertension

Drug therapy to lower blood pressure is indicated in dogs and cats with CKD stages II through IV when blood pressure exceeds 160/100 mm Hg and in dogs and cats with CKD stage I when blood pressure exceeds 180/120. Unless evidence of hypertensive retinal lesions or central nervous system lesions are present, blood pressure values should be determined on at least three separate episodes before establishing the need for therapeutic intervention. The goal of therapy is to reduce blood pressure to at least below 160/100 mm Hg. Untreated, persistently elevated blood pressure may promote progressive renal injury, retinopathy, central nervous system injury, and cardiovascular complications. Elevated blood pressure has been linked to increased mortality in dogs with CKD stages III and IV. In addition, in an induced model of hypertensive CKD, elevated blood pressure was shown to result in reduced renal function, increased proteinuria, and more severe renal lesions.

There is moderate evidence (grade 2) to support a recommendation for amlodipine in managing elevated blood pressure in cats with CKD (Mathur et al., 2002). In cats with induced hypertensive CKD, amlodipine was shown to significantly reduce development of retinal lesions. Amlodipine, the first-choice antihypertensive drug in cats, typically is highly effective in reducing blood pressure in cats, often by as much as 30 to 50 mm Hg. In contrast, there is only weak evidence (grade 4) to support a recommendation to treat elevated blood pressure in dogs with CKD. There are no comparative studies documenting a clinical benefit to treatment of elevated blood pressure in dogs with CKD. Antihypertensive therapy in dogs is recommended based on pathophysiologic justification and extrapolation from observations in humans and rodents. Hypertension in dogs is more resistant to drug therapy than in cats. Because ACE inhibitors such as benazepril and enalapril reduce intraglomerular pressure even when systemic blood pressure is not effectively ameliorated, these drugs are currently considered first-line drugs in dogs with CKD in mitigating the renal effects of hypertension. However, since ACE inhibitors are often ineffective as antihypertensive drugs in dogs, amlodipine is commonly added to ACE inhibitor therapy in an attempt to achieve the therapeutic goal. This combined therapy is particularly important when target organ injury to the eyes or brain is evident. Additional information about hypertensive renal disease can be found in Chapters 159 and 197.

Guideline 12: Provide Calcitriol

Calcitriol is indicated for dogs with CKD stages III and IV to slow progression of CKD and extend survival. However, calcitriol therapy should not begin until the patient's serum phosphorus concentration has been reduced to 6 mg/dl or less. Calcitriol (1,25-dihydroxycholecalciferol), the most active form of vitamin D, is formed in the kidneys by hydroxylation of 25-hydroxycholecalciferol.

Calcitriol deficiency occurs in CKD as a result of the combined effects of phosphorus retention and reduction in renal mass. Renal secondary hyperparathyroidism occurs in large part as a consequence of this deficiency of calcitriol. Calcitriol therapy may induce its clinical effects either indirectly by suppressing hyperparathyroidism or directly by an effect on systemic calcitriol receptors. There is strong evidence (grade 1) to support a recommendation for carefully monitored calcitriol therapy in dogs with CKD (calcitriol was shown to reduce mortality in dogs with CKD in an RCCT comparing calcitriol treatment to placebo). The survival benefit appeared to result from reduced progression of CKD. Studies in human patients with CKD have confirmed a similar survival benefit of calcitriol therapy. There is only weak evidence (grade 4) supporting a recommendation for or against calcitriol therapy in cats with CKD. An RCCT performed in cats with CKD failed to detect a survival benefit of calcitriol therapy. However, this study was a 1-year study, and the possibility that a clinical benefit could have been missed because of the short duration of study compared to the long survival time typical of feline CKD cannot be excluded. There is only weak evidence (grade 4) to support a recommendation for or against using calcitriol to manage clinical signs associated with CKD in dogs or cats. In both the dog and cat RCCT, a benefit of calcitriol in improving appetite, increasing activity, or enhancing quality of life was not detected. See Chapter 193 for more details on these references and appropriate use of this agent.

CHAPTER 191

Acute Renal Failure

LINDA ROSS, *North Grafton, Massachusetts*

Acute renal failure (ARF) is defined as the rapid loss of nephron function (over hours to several days) resulting in azotemia; fluid, electrolyte and acid-base abnormalities; and uremia. Many causes of ARF have been identified in dogs and cats (also see chapter 186). Although supportive therapy is similar regardless of etiology, the prognosis and clinical outcome have been shown to vary, depending on the cause (Vaden, Levine, and Breitschwerdt, 1997).

Classically ARF is divided into three stages. The first (initiation) occurs during and immediately following the renal insult, when pathologic damage to the kidneys is occurring. The latter part of the initiation phase has recently been termed the *extension phase*. During this time ischemia, hypoxia, inflammation, and cellular injury continue, leading to cellular apoptosis and/or necrosis. The initiation phase usually lasts less than 48 hours, during which time clinical and laboratory abnormalities may not be apparent. The second stage (maintenance) is characterized by azotemia and/or uremia and may last for days to weeks. Oliguria (<1 ml of urine per kilogram of body weight per hour) or anuria (no urine production) may occur during the maintenance stage. Urine production can be highly variable. The third stage is recovery, during which time azotemia improves and renal tubules undergo repair. Marked polyuria may occur during this stage as a result of partial restoration of renal tubular function and of osmotic diuresis of accumulated solutes. Renal function may return to normal, or the animal may be left with residual renal dysfunction. It is possible for animals to have ARF with sufficient tubular damage to cause polydipsia and polyuria but not enough nephron loss to cause azotemia.

Treatment of ARF consists of therapy specific for the cause, and supportive therapy based on the stage of ARF and the animal's fluid, electrolyte, and acid-base status. It is important to remember that the doses of drugs

excreted primarily by the kidneys should be reduced or the dosage interval extended in proportion to the degree of azotemia.

SPECIFIC THERAPY

Specific therapy to correct or eliminate the cause of ARF should be instituted if the cause is known or suspected. For example, animals with known ethylene glycol ingestion should have vomiting induced if the ingestion occurred within 3 hours and/or should receive drugs such as 4-methylpyrazole or ethanol to prevent the metabolism of ethylene glycol to its toxic components (Chapter 29). In geographic areas where leptospirosis occurs, all dogs with presumed ARF should receive antibiotics effective against leptospire (penicillin, amoxicillin, or doxycycline). Empiric antibiotic therapy is indicated until pyelonephritis is ruled out by urine or renal tissue culture.

SUPPORTIVE THERAPY

Fluid Therapy

Intravenous fluid therapy remains the mainstay of treatment for ARF. Frequent monitoring of the animal's hydration status, renal function, acid-base status, and electrolytes are necessary to determine appropriate intravenous fluid types and amounts. The increasing availability of in-house or bedside blood chemistry analyzers facilitates such monitoring. Placement of a catheter in the jugular vein allows monitoring of central venous pressure and more precise assessment of intravascular volume status. However, if hemodialysis is a treatment option, the jugular veins should not be used for intravenous catheters or even venipuncture for blood samples; rather they should be preserved for placement of the hemodialysis catheter (see Chapter 194).

The initial volume of fluid to be administered should be calculated based on the animal's body weight and degree of hydration. Water deficits should be replaced within 4 to 6 hours to restore renal blood flow (RBF) to normal as soon as possible. Maintenance fluid requirements (44 to 66 ml/kg/day) and estimated fluid losses from vomiting or diarrhea must be met. Urine production should be monitored during the first few hours of fluid therapy. Placement of an indwelling urinary catheter is the most accurate method for this determination. However, the benefits of an indwelling catheter must be weighed against the risks of ascending infection and (in cats) sedation or anesthesia to place the catheter.

An isotonic, polyionic fluid such as lactated Ringer's solution (LRS) or Plasma-Lyte A (Baxter) may be administered initially. If hyperkalemia is present or suspected because of oliguria or anuria, a potassium-free fluid such as 0.9% sodium chloride is indicated. Following rehydration, the type of fluid should be adjusted based on the animal's fluid and electrolyte status. Polyionic fluids may contain too much sodium for maintenance; and half-strength LRS or 0.45% sodium chloride in 2.5% dextrose may be used for long-term therapy.

Management of Oliguria or Anuria

Once the animal has been hydrated, urine flow should increase rapidly to 2 to 5 ml/kg/hour, depending on the rate of intravenous fluid administration. If urine production is not sufficient, the clinician should first reassess the animal's circulating blood volume. This assessment can include physical examination of hydration status, visual estimation of jugular venous pressure, measurement of PCV and total solids, thoracic radiographs to evaluate cardiac size and pulmonary vascular markings, or ultrasound imaging of the cardiac chambers and hepatic veins. Failure to restore circulating volume to normal is a common reason for decreased urine volume. If the animal is normovolemic, the rate of fluid administration should be slowed to prevent fluid overload and associated adverse effects, particularly respiratory complications related to pulmonary edema. An indwelling urinary catheter should be placed if not already present. Calculation of "ins and outs" can then be used to provide appropriate quantities of intravenous fluids to match urine output. The maintenance fluid requirement (estimated at 20 ml/kg/day for insensible losses) is calculated for a short interval of time, typically 4 hours. The volume of urine produced during the previous time interval is added to the maintenance amount, giving the volume of intravenous fluids to be administered over the subsequent 4-hour period. This regimen helps maintain hydration while minimizing the risk of fluid overload.

Specific therapy to increase urine flow, consisting of administration of one or more diuretics, should next be instituted (Table 191-1). Furosemide is the first diuretic to be administered. Traditionally it has been administered as a bolus at an initial dose of 2 mg/kg intravenously (IV), with escalating doses to 4 to 6 mg/kg at hourly intervals if the initial dose fails to increase urine production. However, a loading dose of 0.66 mg/kg followed by

Table 191-1

Drugs To Promote Urine Production in Animals With Oliguria or Anuria

Drug	Dosage
Furosemide	0.66 mg/kg IV bolus, followed by 0.66 mg/kg/hr CRI or 0.5-1 mg/kg/hr CRI or 2 mg/kg IV bolus If effective, diuresis begins within 15-30 minutes Increase dose to 4-6 mg/kg intravenously at hourly intervals if initial dose does not induce diuresis
Osmotic diuretics	Contraindicated if animal has fluid overload, pulmonary edema, or congestive heart failure
Mannitol 20% Dextrose 20%	0.5-1 g/kg IV bolus slowly, then 1-2 mg/kg/minute IV infusion or repeat bolus every 4-6 hours at a dose of 0.25-0.5 g/kg intravenously or 2 to 10 ml/min for the first 10 to 15 minutes intravenously, then 1 to 5 ml/minute intravenously for a total daily dose of 22 to 66 ml/kg; alternate administration with a polyionic solution
Dopamine	Dogs: 0.5-3 mcg/kg/min CRI intravenously; do not dilute in alkaline solution

CRI, Continuous-rate infusion; IV, intravenous.

continuous rate infusion (CRI) at 0.66 mg/kg/hour has been shown to be more effective in producing diuresis in normal dogs (Adin et al., 2003), and is the protocol I currently use. Others have suggested a CRI of 0.5 to 1 mg/kg/hour.

If furosemide fails to increase urine flow, osmotic diuresis can be attempted. A 20% dextrose solution can be given at 2 to 10 ml/min for the first 10 to 15 minutes, followed by a rate of 1 to 5 ml/min for a total daily dosage of 22 to 66 ml/kg. Administration of hypertonic dextrose should be alternated with a polyionic solution to prevent dehydration from osmotic diuresis. Urine should be monitored for glucose to determine the effectiveness of this therapy. Alternatively, 20% mannitol can be given as a bolus dose of 0.5 to 1 g/kg of body weight over 15 to 20 minutes. If effective, urine flow will increase within 1 hour. Repeat bolus doses can then be administered every 4 to 6 hours, or it can be administered as a CRI at a dose of 1 to 2 mg/kg/min. Mannitol may have additional beneficial effects in addition to its action as a diuretic. It inhibits renin release because of its hyperosmolar effect on tubular luminal filtrate. In addition, it acts as a free-radical scavenger, blunts damaging increases in intramitochondrial calcium, and may result in a beneficial release of atrial natriuretic peptide. Because mannitol is not metabolized, its effects remain in the intravascular space longer than those of dextrose. Administration of hypertonic solutions

is contraindicated in oliguric animals that are overhydrated because it results in increased serum osmolality, circulating blood volume, and blood pressure.

Dopamine infusion has traditionally been recommended for oliguric or anuric animals. Dopamine stimulates two types of dopamine receptors (DA-1 and DA-2) as well as α - and β -adrenergic receptors. In dogs it causes an increase in RBF and urine volume; glomerular filtration rate (GFR) either increases or is unchanged. In cats increased urine production occurs in the absence of increases in RBF or GFR. This is most likely caused by α -adrenergic stimulation, which increases cardiac output and blood pressure and induces natriuresis. The benefit of dopamine infusion in humans with or at risk of ARF has come under increasing scrutiny. Dopamine has been used in humans because it was thought to increase RBF and therefore reduce ischemic damage to renal tubules. However, the etiology of ARF in humans with critical illnesses is now believed to be multifactorial. A recent meta-analysis found that dopamine infusion did not prevent mortality or need for dialysis and concluded that the use of dopamine for the treatment (or prevention) of ARF could not be justified and should be eliminated from routine clinical use (Kellum and Decker, 2001). There is little or no documentation of the efficacy of dopamine in dogs and cats with ARF. It may have some benefit in dogs with oliguria or anuria because increasing urine production is beneficial in managing fluid therapy. Its use in cats is less clear because the higher doses necessary to promote urine production may result in adverse physiologic consequences (see following paragraphs) that may negate its benefit.

For dogs dopamine is diluted in an isotonic fluid and administered as an intravenous infusion at the rate of 0.5 to 3 mcg/kg/min. High rates of infusion (greater than 10 mcg/kg/min) are to be avoided because they may cause arrhythmias, increased blood pressure, and vasoconstriction. The last may reduce RBF as well as that to other organs. Sodium bicarbonate should not be added to the fluids since dopamine is inactivated in alkaline solutions. Electrocardiographic monitoring is recommended during dopamine infusion because of its arrhythmogenic properties. If arrhythmias occur, discontinuation of the drug for 30 to 60 minutes and reinfusion at a lower rate usually alleviate the problem. Furosemide may be administered concurrently with dopamine. The combination has been shown to be synergistic in maintaining GFR, RBF, and urine flow in dogs with experimental ARF and to reduce the severity of some forms of experimental ARF when administered before the renal insult. If oliguria persists despite these measures, dialysis would be the next therapeutic step.

Recently a selective DA-1 agonist (fenoldopam) has become available. Preliminary studies of its renoprotective effects in people have been promising. One experimental study in healthy cats found that an infusion of 0.5 mcg/kg/min produced more diuresis than dopamine (Simmons et al., 2006). However, a study in experimental dogs undergoing nephrotomy showed no difference in GFR or urine volume between dogs receiving fenoldopam or saline (Zimmerman-Pope et al., 2003). No clinical studies have been reported in dogs or cats with ARF,

and its role in management of oliguric ARF is not yet known.

Corrections of Acid-base and Electrolyte Abnormalities

Metabolic acidosis occurs in ARF. Alkalinizing therapy is not recommended unless the blood pH is less than 7.2 or the serum bicarbonate is less than 14 mEq/L after correcting fluid deficits because it can result in significant complications, including paradoxical cerebrospinal fluid acidosis, decreased ionized serum calcium, and hyponatremia. If necessary, the bicarbonate deficit is calculated as:

$$\text{Body weight (kg)} \times 0.3 \times (24 - \text{measured bicarbonate}) \\ = \text{mEq bicarbonate deficit.}$$

One-quarter of the deficit is added as sodium bicarbonate to the intravenous fluids over 12 hours, and acid-base status reassessed before further administration.

Moderate-to-severe life-threatening hyperkalemia may occur if the animal is oliguric or anuric. The first and most important step in therapy for hyperkalemia is to ensure urine production and excretion. Animals with severe hyperkalemia or those in which oliguria persists may benefit from additional specific therapy such as sodium bicarbonate, regular insulin, and glucose, or in life-threatening situations calcium gluconate. Hypokalemia may occur during the diuretic phase of ARF. Therapy consisting of intravenous or oral potassium chloride is indicated if the serum potassium concentration is below the normal range, although clinical signs are not usually apparent until it falls below 2.5 mEq/L.

Treatment of Other Uremic Signs

Vomiting can be a significant problem in animals with ARF. Drugs that inhibit gastric acid production are indicated because uremia results in hypergastrinemia. Such drugs include histamine receptor antagonists such as famotidine (0.5 to 1 mg/kg q24h orally [PO]) and proton pump inhibitors such as omeprazole (Prilosec OTC, Procter & Gamble) (0.7 mg/kg q24h PO or lansoprazole (Prevacid, TAP Pharmaceutical Products Inc.) (0.6 to 1 mg/kg q24h IV). Centrally acting antiemetics may also be necessary. Metoclopramide, a dopamine antagonist, may be given as intermittent therapy at a dosage of 0.2 to 0.5 mg/kg q8h IV or as a CRI at 1 to 2 mg/kg/day IV. Other centrally acting drugs include dolasetron (Anzemet, Aventis Pharmaceuticals) (0.6 mg/kg q24h PO or subcutaneously [SQ]) or diluted in compatible intravenous fluid and administered over 15 min IV) and ondansetron (Zofran, GlaxoSmithKline) (0.1 to 0.2 mg/kg q8h SQ or 0.5 mg/kg intravenous loading dose and then 0.5 mg/kg/hr CRI). Phenothiazine derivative antiemetics such as chlorpromazine (0.2 to 0.5 mg/kg q6–8h, SQ, intramuscularly, or IV) can be tried if vomiting persists despite other therapy. Side effects of phenothiazines include sedation and decreased blood pressure. A newer NK1 antagonist, maropitant (Cerenia, Pfizer) (1 mg/kg q 24h, SQ for up to 5 days), is effective as a central and peripheral acting antiemetic in treating nausea and vomiting from renal failure.

Hypertension

Arterial hypertension is common in animals with ARF and is often the result of fluid overload. Treatment includes reducing the rate of intravenous fluid administration, administration of diuretics, and dialysis to remove excess fluid if the animal is oliguric or anuric. Pharmacologic treatment is limited because most antihypertensive drugs are available only in oral formulations and the vomiting associated with ARF often precludes oral medication. If hypertension is severe, parenteral antihypertensives include nitroprusside (initial dose 1 to 2 mcg/kg/min CRI IV; titrate up q5min to achieve desired blood pressure) and hydralazine (0.5 to 3 mg/kg q12h IV or 0.1 mg/kg loading dose IV and then 1.5 to 5 mcg/kg/min CRI IV). Administration of both drugs requires close monitoring. Oral antihypertensives include amlodipine (Norvasc, Pfizer) (0.1 to 0.25 mg/kg q12–24h PO in dogs; 0.625 to 1.25 mg/cat q24h PO in cats) and angiotensin-converting enzyme (ACE) inhibitors such as enalapril (0.25 to 0.5 mg/kg q12–24h PO) and benazepril (Lotensin, Novartis) (0.25 to 0.5 mg/kg q24h PO). ACE inhibitors have been associated with worsening of renal function in humans.

Nutritional Management

Nutritional support has been shown to be important for recovery from ARF. These animals are in a state of negative nutritional balance at a time when protein and energy are needed to support regeneration of damaged renal tissue. Enteral nutrition via an esophagostomy or gastrostomy tube can be used if the animal is not vomiting (see Chapter 196); otherwise parenteral nutrition is indicated.

Prognosis and Duration of Treatment

The prognosis for dogs and cats with ARF depends on the cause and the response to therapy. Those in which the cause is identified and treated early in the course of the disease (e.g., pyelonephritis and leptospirosis) have a relatively good prognosis. Animals with ethylene glycol toxicity that are already azotemic when diagnosed have been shown to have a poor-to-grave prognosis, even with

therapy. Other criteria that have been shown to confer a poor prognosis include severe azotemia (serum creatinine >10 mg/dl), lack of improvement or worsening of azotemia with appropriate fluid and supportive therapy, and concurrent systemic disease such as pancreatitis or sepsis.

Supportive and specific treatment should be continued until one of the following occurs: (1) renal function returns to normal; (2) renal function improves and stabilizes, although not to normal levels, and the animal is doing well clinically; (3) renal function worsens, fails to improve, or does not improve sufficiently for the animal to be managed medically at home for the resulting renal insufficiency. In the first two scenarios fluid therapy can be tapered, and other supportive medications adjusted in response to the animal's clinical signs. In the third scenario dialysis may be considered to support the animal for a longer period of time to see if renal function will improve. If dialysis is not an option, euthanasia may be indicated at this point.

Chronic Kidney Disease: Staging and Management

JONATHAN ELLIOTT, *London, United Kingdom*

A.D.J. WATSON, *Glebe, New South Wales, Australia*

The International Renal Interest Society (IRIS) was formed to undertake the task of producing tools to help practitioners better diagnose, stage, and treat chronic kidney disease (CKD) in dogs and cats.* The group has formulated consensus positions based on their own clinical experience and recommendations made by expert panels that have reported recently on hypertension and proteinuria.† The results of these deliberations are described here.

DIAGNOSIS OF KIDNEY DISEASE

Kidney disease is identified in patients examined because of illness or screened because of their age. Fig. 192-1 presents a decisional algorithm for the diagnosis of kidney disease. The classic findings suggestive of kidney disease recognized by members of the IRIS group are presented in Box 192-1. Many but not all of these abnormalities may have been noted by the owner over a relatively long period (weeks to months), perhaps gradually becoming more noticeable if the disease is truly chronic; but not all animals show classic signs of CKD.

When faced with an animal suspected of having CKD, practitioners should adopt a logical approach to diagnosis. The recommended minimum database to be collected from such patients is shown in Fig. 192-2. During this process it is helpful to review the historical and physical abnormalities that led to this suspicion since these and other available evidence may highlight specific problems that warrant further investigation to determine the type of kidney disease present. This review may also indicate whether an underlying cause is likely to be identified by further investigations and whether concomitant diseases should be suspected.

The laboratory database obtained should include appropriate blood biochemistry tests, hematologic examination, and complete urinalysis. These should serve to confirm the clinical diagnosis but may also give indications of the etiology and possible presence of underlying diseases. The results also enable classification of the kidney disease, with the aim of facilitating treatment decisions and providing a prognosis for the owners. Because kidney disease increases in prevalence as dogs and cats age, the practice of running geriatric screens to detect kidney dysfunction has become

more widespread in veterinary practice. The IRIS minimum recommended geriatric screen for this purpose is presented in Box 192-2, together with a more ideal complete version.

The key factor in the proposed staging system is the blood creatinine concentration, determined in plasma or serum when the patient is fasted and well hydrated. Because the staging applies only to CKD, it is imperative for other possible causes of increased creatinine concentrations (acute renal failure, prerenal and postrenal azotemia) to be excluded (Fig. 192-3). Furthermore, the creatinine concentration should be stable, ideally over several days or weeks, because staging is inaccurate if azotemia is changing in severity. CKD is generally accompanied by relatively long-standing clinical signs of kidney disease (see Box 192-1). If these signs have been present in an animal that is acutely sick and has an unstable plasma creatinine concentration, it may be suffering an acute uremic crisis. One should manage this crisis and wait until blood creatinine concentration is stable before attempting to stage the disease. Acutely ill dogs and cats with renal azotemia (acute renal failure) but no clinical history compatible with CKD may stabilize after treatment with persistent abnormalities in kidney function. These cases should be staged once the plasma creatinine concentration is stable over a 2- to 4-week period.

Although blood creatinine concentration is considered a relatively crude index of glomerular filtration rate (GFR), it is currently the best GFR indicator available in routine practice. In future iterations of the staging system, the basal creatinine concentration might be replaced by a more precise indicator. Another potential future modification concerns the patient's muscle mass. This governs the production rate of creatinine and thereby influences its blood concentration. Thus cachexia with marked loss of lean body mass leads to lowered creatinine production and may cause underestimation of the severity of kidney dysfunction, particularly in cats. The opposite may occur in well-muscled individuals. The importance of these changes has yet to be assessed, but it is something to consider when staging borderline cases. Staging on blood creatinine concentration should be followed, if possible, by further substaging on the basis of proteinuria and blood pressure since both of these factors may influence treatment selection and prognosis.

STAGES OF CHRONIC KIDNEY DISEASE

The staging system for CKD developed as an IRIS consensus document and was modified following use by

*The IRIS group recommend the use of the term *chronic kidney disease* in place of *chronic renal failure* to bring the veterinary profession in line with current terminology used in human medicine.

†Members of the IRIS Board are listed at www.IRIS-Kidney.com.

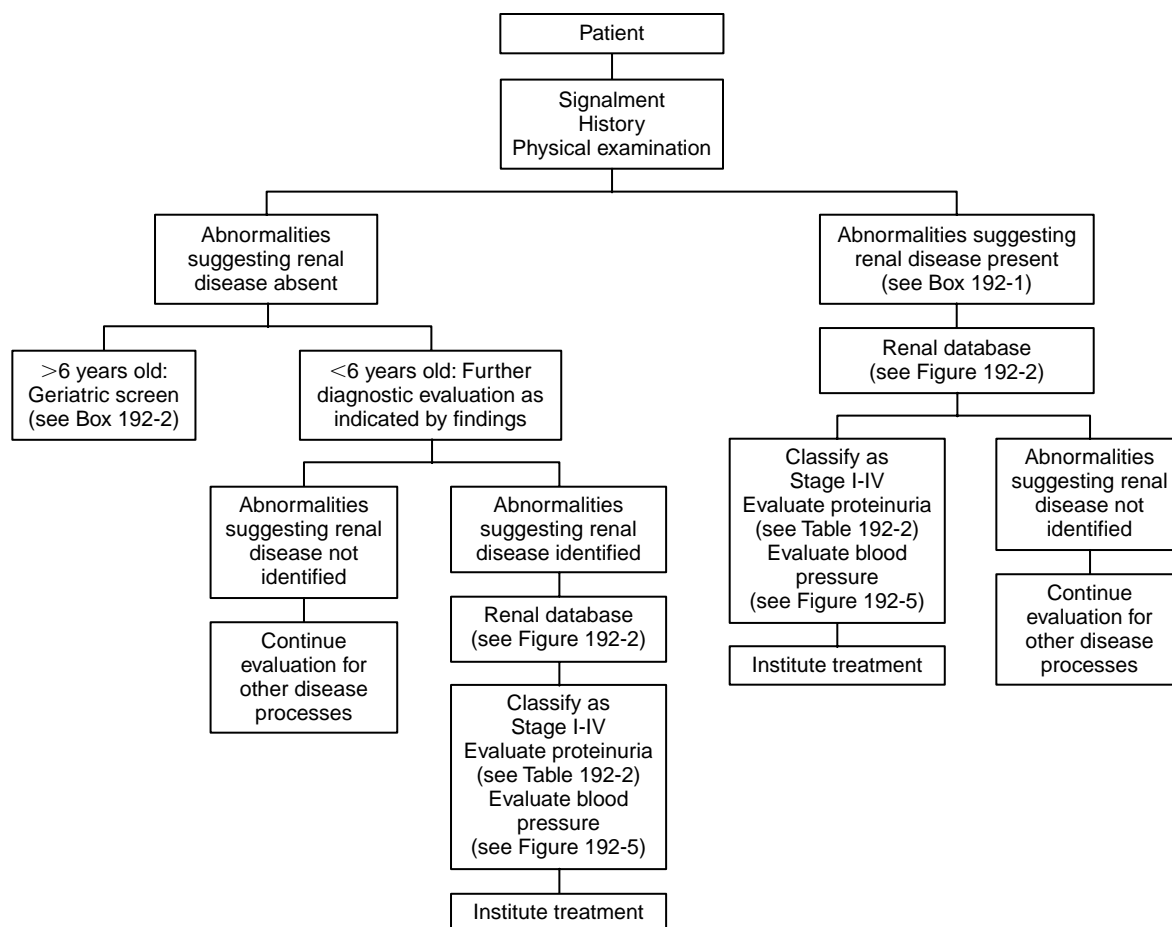

Fig. 192-1 Decisional algorithm for diagnosis of chronic kidney disease.

IRIS Board members in clinical practice and discussion with members of the American and European Societies of Veterinary Nephrology and Urology. This has resulted in separate but similar algorithms for staging CKD in cats and dogs (Fig. 192-3 and Table 192-1) categorizing the severity of disease as is done with congestive heart failure. This system and the associated treatment recommendations should help veterinary practitioners diagnose, understand, and treat CKD. In the longer term, consistent and widespread application of staging should facilitate collection and analysis of clinical data from various sources, thereby improving knowledge of causes, consequences, and treatments of CKD in cats and dogs.

SUBSTAGES OF CHRONIC KIDNEY DISEASE

Proteinuria

The goal is to identify renal proteinuria, having first ruled out potential prerenal and postrenal causes. Ideally the urine protein/creatinine (UP/C) ratio should be measured in all cases, provided there is no evidence of urinary tract inflammation or hemorrhage and plasma protein evaluation has ruled out dysproteinemias. Renal proteinuria can be of glomerular or tubular origin. Patients are classified

as proteinuric (P), nonproteinuric (NP) or borderline (BP), as shown in Table 192-2.

The IRIS algorithm for substaging on proteinuria reflects the recent ACVIM Consensus Statement on renal proteinuria (Lees et al., 2005) and is presented in Fig. 192-4. Ideally decisions should be made on the basis of at least three urine samples collected over a period of at least 2 weeks. This will determine whether proteinuria is transient (and therefore likely to be functional/physiologic) or persistent (and therefore likely to be pathologic and of tubular or glomerular origin). The higher the UP/C ratio, the more likely the animal is to have primary glomerular disease. Patients with persistent proteinuria in the BP substage should be reevaluated within 2 months and reclassified as appropriate. Proteinuria may decline as renal dysfunction worsens and thus may be less frequent in CKD stages III and IV. Response to any treatment given to reduce glomerular filtration pressure and proteinuria should be monitored at intervals using the UP/C ratio.

A finding of persistent proteinuria probably has important implications for the potential benefits of both dietary and pharmacologic management of CKD in the dog and cat. Recent evidence suggests that the severity of proteinuria is inversely related to the occurrence of uremic crises and renal mortality in dogs

Box 192-1

Abnormalities Suggestive of Kidney Disease***History**

- Signalment (breed, age, gender)
- Polydipsia/polyuria
- Loss of body weight
- Reduced or irregular appetite
- Hair coat changes
- Vomiting
- Lethargy
- Exercise intolerance
- Decline in sociability or other behavioral changes
- Recent travel to region endemic for infectious renal disease
- Current or previous therapy with effects on renal function
- Blindness (especially if sudden onset)

Physical Examination

- Pale mucous membranes, dehydration
- Abnormal hair coat
- Dental calculus, gingivitis, periodontitis
- Oral ulceration, stomatitis, halitosis, uremic breath
- Abnormal renal palpation (small, firm and irregular, or enlarged)
- Abnormal rectal palpation (prostate or urethra)
- High systemic arterial blood pressure
- Ocular changes consistent with hypertension
- Decline in body weight or low body condition score
- Evidence of osteodystrophy (e.g., pliable mandible, fractures with little or no trauma, bone pain)
- Edema

*There is considerable interanimal variability and not all these findings may be present in an individual with kidney disease.

Box 192-2

Geriatric Screen (for All Dogs and Cats More Than 6 Years Old)

- Minimum
 - Hematocrit
 - Total solids
 - Urinalysis
 - Creatinine
 - Urea
- More complete
 - Complete hematology
 - Full biochemical panel
 - Complete urinalysis

(Jacob et al., 2005) and all-cause mortality in cats (Syme et al., 2006). Experimental evidence supports the beneficial effects of dietary therapy (particularly n-3 polyunsaturated fatty acid [PUFA] supplementation; Brown et al., 1998) and angiotensin-converting enzyme inhibitor (ACEI) therapy in dogs and ACEI therapy in cats in lowering UP/C ratio and glomerular filtration pressures, limiting structural changes in remnant kidneys, and/or slowing the decline in GFR. Clinical studies also suggest beneficial effects of dietary intervention (n-3 PUFA supplementation and restriction of protein, phosphate, and sodium intake) in dogs (Jacob et al., 2002) and cats (Elliott et al., 2000; Plantinga et al., 2005). However, all of these studies involved clinical kidney diets rather than manipulation of single dietary components; thus the precise factor(s) responsible for the outcomes cannot be determined. Similarly, clinical studies in dogs and cats confirm the beneficial effects of ACEI therapy (Grauer et al., 2000; King et al., 2006). The IRIS recommendations on substaging result from this accumulating evidence and are linked to the treatment recommendations specifically addressing proteinuria in the following paragraphs.

Blood Pressure

Measurement of blood pressure is important in substaging CKD in dogs and cats. The kidney is at risk of damage from hypertension. Although systemic arterial blood pressure is labile and varies according to physiologic state, hypertension is defined as a blood pressure that causes harm. The 2003 ACVIM Consensus Statement on blood pressure defined pressures that, in the experience of the cardiologists, nephrologists, neurologists and ophthalmologists involved, were associated with end-organ damage (Brown et al., 2007). The four organs most prone to damage from systemic hypertension are the heart, kidneys, brain, and eyes. Table 192-3 defines blood pressure ranges associated with minimal, low, moderate, and severe risk of end-organ damage. The algorithm in Fig. 192-5 shows the IRIS group's recommendations for using these data, together with relevant clinical findings in substaging cases of canine and feline CKD.

History Water intake Body weight Food intake Vomiting	Laboratory Obtain samples prior to therapy <i>Hematology</i> (at least): <ul style="list-style-type: none"> • Hematocrit • Reticulocyte count • Total solids by refractometry
Physical examination Body temperature Hydration status Body weight and body condition score Mucous membrane color Kidney palpation Coat condition Oral examination Rectal palpation Fundic examination Thyroid palpation (cat) Blood pressure (if available)	<i>Blood biochemical tests</i> (at least): <ul style="list-style-type: none"> • Creatinine • Urea (blood urea nitrogen) • Phosphate • Calcium and albumin • Bicarbonate (or total carbon dioxide) • Potassium <i>In cats > 10 years old:</i> check ALT and screen for hyperthyroidism <i>Urinalysis</i> (at least): <ul style="list-style-type: none"> • Cystocentesis preferred (record method) • Dipstick of supernatant to determine pH, glucose, hemoglobin, protein • Specific gravity by refractometry • Sediment examination (centrifuge at least 3 ml of urine)

Fig. 192-2 Minimal database for patients with signs of kidney disease.

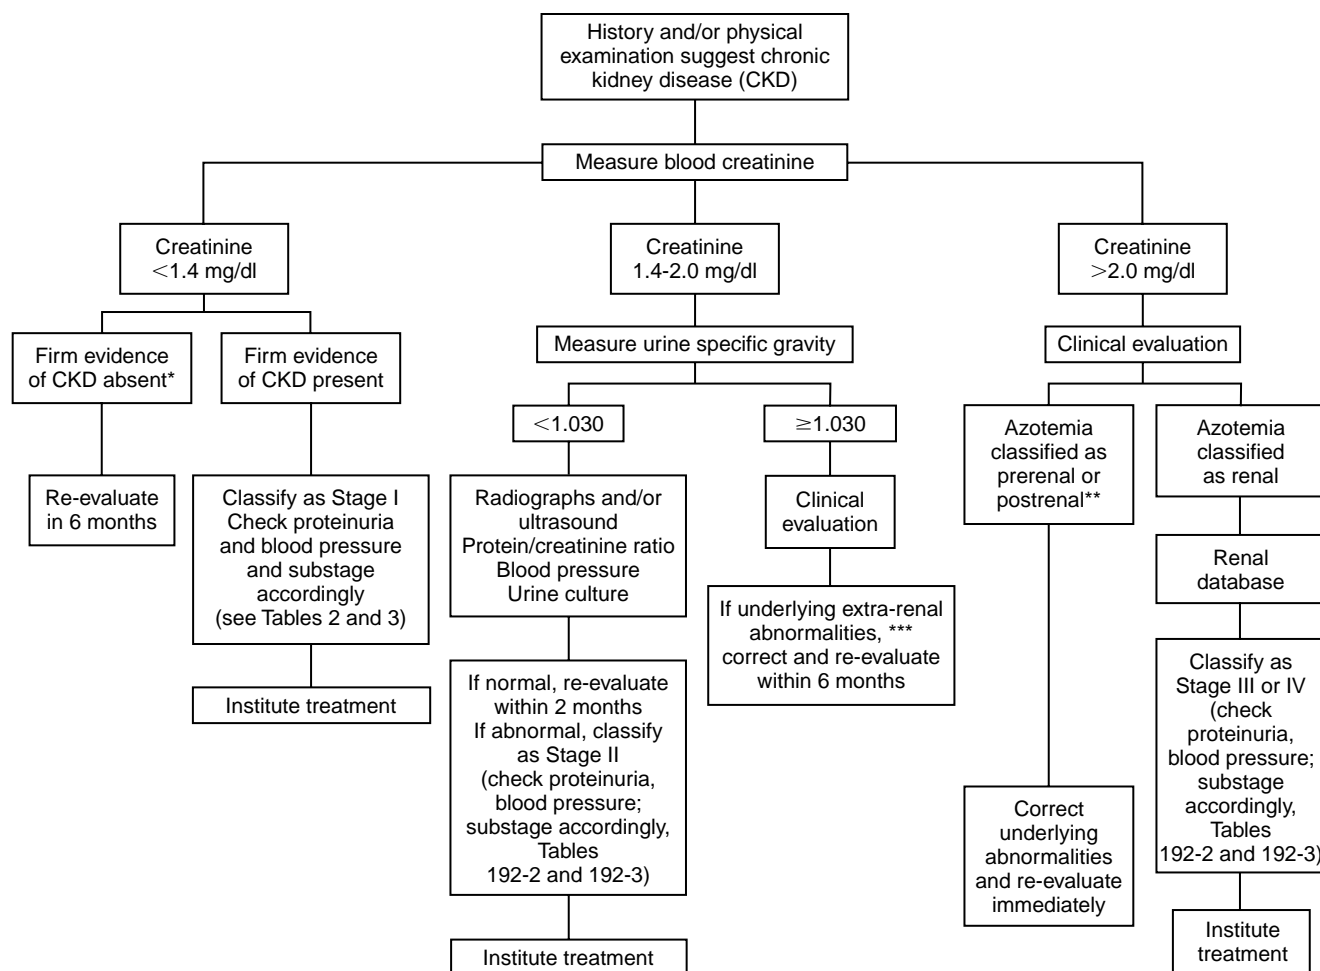

Fig. 192-3 Staging for chronic kidney disease. The algorithm for dogs is shown; the algorithm for cats is similar but uses the creatinine concentrations shown in Table 192-1 and a urine specific gravity of ≥ 1.035 as an indicator of concentrating ability.

Table 192-1

Staging on Blood Creatinine Concentration

Stage	Creatinine (mg/dl) ($\mu\text{mol/l}$)	Comments
I	<1.4 (125) dogs <1.6 (140) cats	Nonazotemic Some other renal abnormality present (e.g., inadequate urinary concentrating ability without identifiable nonrenal cause; abnormal renal palpation and/or abnormal renal imaging findings; proteinuria of renal origin; abnormal renal biopsy results; increasing blood creatinine concentrations in samples collected serially)
II	1.4-2 (125-180) dogs 1.6-2.8 (140-250) cats	Mild renal azotemia (lower end of the range lies within reference ranges for many laboratories, but the insensitivity of creatinine as a screening test means that animals with creatinine values close to the upper reference limit often have excretory failure) Clinical signs usually mild or absent
III	2.1-5 (181-440) dogs 2.9-5 (251-440) cats	Moderate renal azotemia Many extrarenal clinical signs may be present
IV	>5 (>440) dogs and cats	Severe renal azotemia Many extrarenal clinical signs are usually present

The IRIS group does not specify the method to be used for blood pressure measurement. The type of equipment used, the protocol followed (probably more important), and the conditions in the practice when measurements are done undoubtedly affect the values obtained and

the reproducibility of results between sessions. However, blood pressures persisting in the moderate- or high-risk range on three occasions over at least 2 weeks suggest that therapeutic intervention may be warranted, even if end-organ damage is not apparent.

Table 192-2

Substaging on Urine Protein/Creatinine (UP/C) Ratio

UP/C Value*	Interpretation
<0.2 dogs and cats	Nonproteinuric (NP)
0.2-0.4 cats 0.2-0.5 dogs	Borderline proteinuric (BP)
>0.4 cats >0.5 dogs	Proteinuric (P)

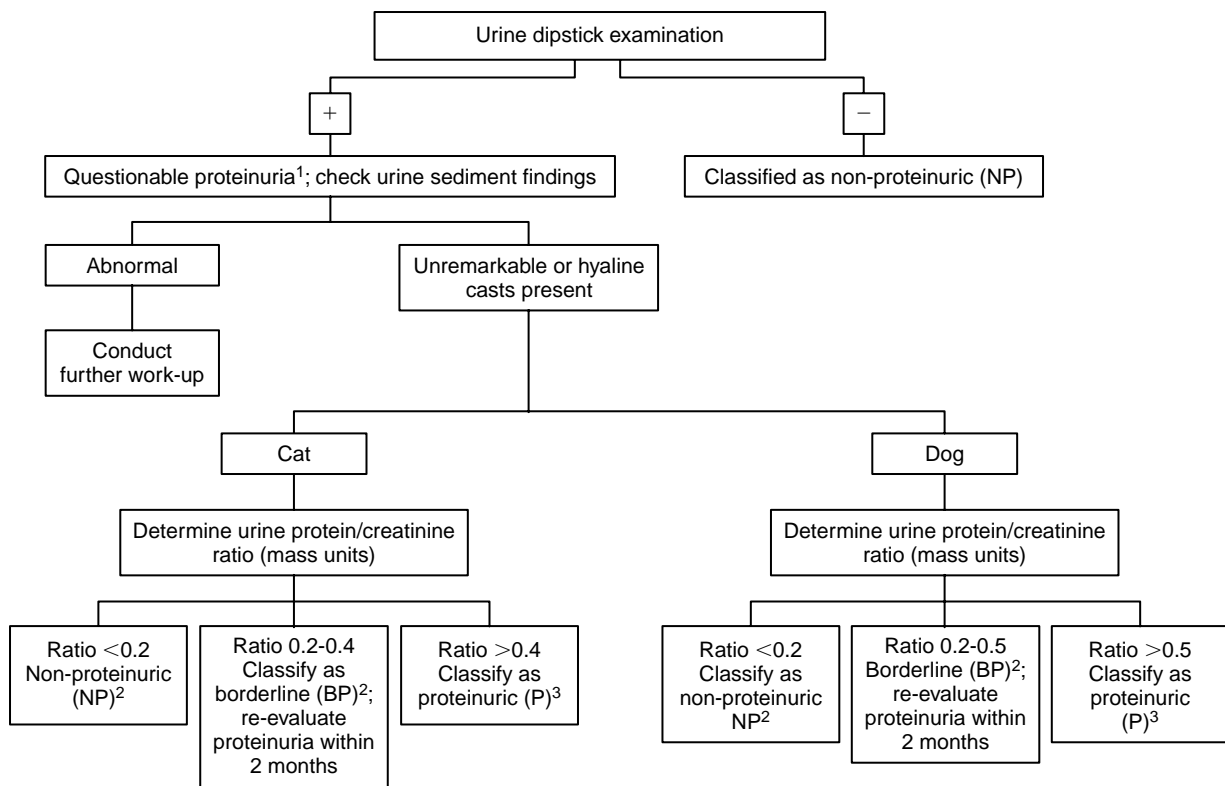

*Calculated using mass units.

COMBINING CHRONIC KIDNEY DISEASE STAGES AND SUBSTAGES

The IRIS scheme allows CKD in dogs and cats to be staged on the basis of the fasting blood creatinine concentration and further characterized according to urine protein content and systemic blood pressure, as shown in the following examples:

1. A proteinuric (UP/C ratio 0.7) dog with systolic blood pressure of 120 mm Hg and blood creatinine concentration 3.4 mg/dl would be classified as stage III-P-N (where P denotes proteinuric and N denotes blood pressure status with minimal or no associated risk of end-organ damage).
2. A dog with borderline proteinuria (UP/C ratio 0.35) and blood creatinine concentration of 5.4 mg/dl that did not have blood pressure assessment would be classified as stage IV-BP-RND (where BP denotes borderline proteinuria and RND denotes that the risk of end-organ damage associated with blood pressure has not been determined).
3. A nonproteinuric (UP/C ratio 0.12) cat with systolic blood pressure of 210 mm Hg having bilateral retinal detachments and blood creatinine concentration of 2 mg/dl would be classified as stage II-NP-Hc (where NP denotes nonproteinuric and Hc denotes blood pressure associated with a high risk of end-organ damage and existing complications of end-organ damage).

It should then be possible to make empiric recommendations about treatments that can logically be considered for the patient and to prognosticate on the likely response to such therapy based on accumulated clinical experience.

1. Standard urine dipstick tests can give false positive results (particularly 1+); practitioners should consider using a more specific screening test (e.g., sulphosalicylic acid turbidometric test or the ERD test (Heska Ltd.).
2. UP/Cs in the NP or BP range may be categorized as "microalbuminuric" on the ERD test; the significance of microalbuminuria in predicting future renal health is not understood at present; the IRIS recommendation is to continue to monitor this level of proteinuria.
3. Proteinuria of this magnitude requires therapeutic intervention in CKD Stages II to IV.

Fig. 192-4 Urine dipstick examination.

Table 192-3

Substaging on Blood Pressure		
Risk*	Systolic (mm Hg)	Diastolic (mm Hg)
Minimal	<150	<95
Low	150-159	95-99
Moderate	160-179	100-119
High	≥180	≥120

*Risk = likelihood that high pressure will further damage the kidney and other end-organs (i.e., heart and blood vessels, brain, and chorioretina).

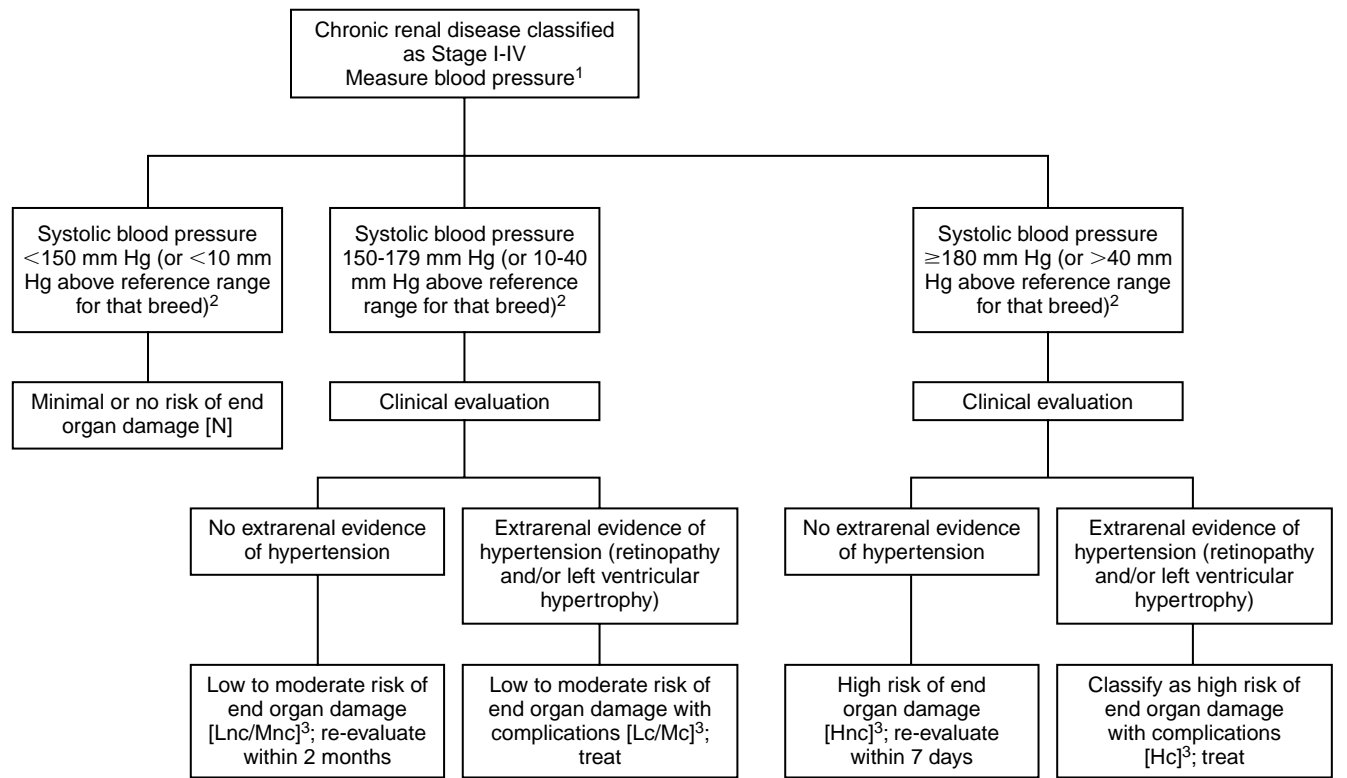

RECOMMENDATIONS FOR TREATING CHRONIC KIDNEY DISEASE IN DOGS AND CATS

Empirical recommendations developed, through consensus of the IRIS group, for management of CKD in dogs

and cats according to stage are presented in Table 192-4. They represent suggested starting points and should always be tailored to the individual patient. Frequent monitoring and readjustment of therapy according to response are the keys to success. As many of the complications of CKD increase in prevalence with the stage, so the intensity of treatment required also increases.

General Management for Patients Diagnosed With CKD

- Discontinue all potentially nephrotoxic drugs
- Identify and treat any prerenal and postrenal abnormalities
- Rule out any treatable conditions within the urinary tract (e.g., renal urolithiasis and pyelonephritis)
- Rule out any treatable underlying disease outside the urinary system that can perpetuate renal damage (e.g., hyperthyroidism, hyperadrenocorticism, pyometra)

1. Blood pressure should be evaluated using a standard protocol that accounts for difficulties associated with indirect measurement of blood pressure. This should include patient acclimation to measurement conditions and multiple measurements during each measurement session. Because prognosis and therapy depend on this assessment, the final classification should rely on multiple pressure determinations (preferably involving repeat visits to the clinic on separate days, but “acceptable” if done during the same visit with at least 2 hours between determinations). This algorithm only classifies on the basis of systolic blood pressure, but Table 192-3 provides definitions based on systolic and diastolic pressures. In many cases both values will fall in the same category. When they do not, classification should be that of the higher category.

2. Comparison should be made with the upper limit of the breed-specific reference ranges, where available. Sight hounds, in particular, have higher reference ranges than most other dog breeds.

3. Patients are classified according to risk of end organ damage (see Table 192-3) and actual presence of extrarenal end organ damage or complications (e.g., hypertensive ocular lesions and/or left ventricular hypertrophy). Patients are then categorized according to the level of risk (N, minimal or none; L, low; M, moderate; H, high) and whether there is evidence of end organ damage/complications (nc, no complications; c, complications). Thus a patient with systolic blood pressure of 165 mm Hg and hyphema would be substaged as Mc (moderate risk with end organ complications). If blood pressure is not determined, the patient is classified as “blood pressure risk not determined” (RND).

Fig. 192-5 Algorithm for substaging on systemic blood pressure.

Table 192-4

Treatment Recommendations According to Stage of Chronic Kidney Disease

Stage	Complications to Address	Recommended Approach in the Dog	Differences in the Cat	Monitoring Required to Detect Adverse Events
I	Dehydration	See general comments in text	As for dog	See comments in text
	Systemic hypertension	See general comments in text	Treatment approach differs (see text for details)	See comments in text
	Proteinuria	If UP/C >2.0, investigate for disease processes leading to proteinuria*† and start antiproteinuric therapy‡§	As for dog	ACEI use is contraindicated in any animal that is clinically dehydrated and/or showing signs of hypovolemia
		UP/C >1.0 but <2.0 requires thorough investigation,*† and close monitoring¶ UP/C >0.5 but <1.0 requires close monitoring¶	As for dog Close monitoring should start at UP/C >0.4	Correct dehydration before using these drugs otherwise GFR may drop precipitously
II	Dehydration	See general comments in text	As for dog	See comments in text
	Systemic hypertension	See general comments in text	Treatment approach differs (see text for details)	See comments in text
	Proteinuria	Recommendations as for stage I except intervention point for antiproteinuric therapy‡§ is UP/C >0.5	As for dog except treatment should commence if UP/C is >0.4	See comment about ACEI use for stage I
		UP/C >0.2 but <0.5 requires close monitoring¶	UP/C <0.2 but <0.4 requires close monitoring	
	Metabolic acidosis	If blood HCO ₃ /TCO ₂ is <18 mEq/L once patient is stabilized on diet of choice, give oral sodium bicarbonate or potassium citrate to maintain blood HCO ₃ /TCO ₂ at 18-24 mEq/L	Intervention point for treatment of metabolic acidosis is blood HCO ₃ /TCO ₂ of 16 mEq/L	Treatment with phosphate binders should be to effect, with signs of toxicity limiting the upper possible dose rate in each patient
	Hypokalemia	Not a problem in dogs with CKD	If the patient is hypokalemic, give potassium gluconate orally to correct this (typically 1-2 mEq/kg/day)	Monitor blood calcium and phosphate concentrations every 4-6 weeks until stable and then every 12 weeks
III	Hyperphosphatemia/hyperparathyroidism	Chronic reduction of phosphate intake to maintain plasma phosphate concentration at 2.7-4.5 mg/dl (0.9 to 1.45 mmol/L) is beneficial to patients with CKD—by first restricting dietary phosphate intake and then by adding intestinal phosphate binders¶ if required	Cats in stage 2 have normal plasma phosphate concentrations but often have increased plasma PTH concentration	Microcytosis and/or generalized muscle weakness suggests aluminium toxicity if using an aluminium containing binder; switch to another form of phosphate binder should this occur. Hypercalcemia should be avoided; combinations of aluminium and calcium containing phosphate binders may be necessary in some cases
	Systemic hypertension	As for stage II	As for stage II	See stage II
	Proteinuria			
	Metabolic acidosis			
	Hypokalemia			
	Dehydration	As for stage II— routine, regular administration of parenteral fluids could be considered to prevent dehydration	As for dog	Calculate daily fluid requirements carefully and avoid overhydration or sodium overload

(Continued)

Table 192-4—Cont'd

Treatment Recommendations According to Stage of Chronic Kidney Disease

Stage	Complications to Address	Recommended Approach in the Dog	Differences in the Cat	Monitoring Required to Detect Adverse Events
	Hyperphosphatemia/hyperparathyroidism	If plasma phosphate exceeds 4.5 mg/dl (1.45 mmol/L) after maximum palatable phosphate binder dose has been achieved and hyperparathyroidism (increased blood PTH concentration) is documented, consider using ultralow dose calcitriol (1.5 to 3.5 ng/kg/day); evidence suggests judicious use prolongs survival in dogs at stages III and IV when phosphate is controlled and ionized calcium and PTH are monitored	Beneficial effects of ultralow dose calcitriol have not been established in cats	Monitor blood ionized calcium and phosphate and avoid hypercalcemia
	Raised plasma urea concentration	Restrict dietary protein if blood urea is >30 mmol/L to decrease urea concentration	As for dog, but level of protein to be fed will be higher	Avoid protein malnutrition; monitor body condition score
	Anemia	Consider treatment for anemia if affecting patient's quality of life (typically with PCV ≤ 20% [0.20 I/I]). Human recombinant erythropoietin is the most effective treatment but is not approved for veterinary use. Anabolic steroids are of no proven benefit and may be detrimental	As for dog	Monitor PCV to avoid erythrocytosis and to detect when patient is becoming refractory to treatment
	Nausea and vomiting	Treat with H ₂ receptor blocker (e.g., ranitidine) and antiemetic (e.g., metoclopramide)	As for dog, although vomiting is less common	
	Drug therapy	Drugs that rely predominantly on renal function for elimination should be used with caution in CKD stages III and IV; it may be necessary to adjust dose of these drugs (depending on their therapeutic indices) to avoid accumulation	As for dog	
IV	All complications listed under Stage III apply	All recommendations made for stage III apply to stage IV, but as azotemia worsens, need to: (a) Intensify efforts to prevent protein/calorie malnutrition. (could consider placing feeding tube—e.g., percutaneous gastrostomy tube) (b) Intensify efforts to prevent dehydration (can administer fluids as well as food through tube) (c) Consider dialysis, renal transplantation, or euthanasia	As for dog; recommendations for stage III in cat also apply	As for stage III Do not introduce ACEI to unstable, dehydrated animal; GFR may drop precipitously if used before patient is adequately hydrated

ACEI, Angiotensin-converting enzyme inhibitor; CKD, chronic kidney disease; GFR, glomerular filtration rate; HCO₃, bicarbonate; PCV, packed cell volume; PTH, parathyroid hormone; TCO₂, total carbon dioxide; UP/C, urine protein/creatinine ratio.

*Look for any concurrent associated disease or process that can be treated or corrected.

†Consider kidney biopsy to help identify underlying disease (consult expert if unsure of indications for biopsy).

‡ACEI with dietary n-3 PUFA supplementation and dietary protein restriction.

§ACEI Low-dose aspirin (0.05-0.5 mg/kg/day) if serum albumin is < 2 g/dl (20 g/L).

¶Monitor response to treatment/progression of disease: stable plasma creatinine concentration and decreasing UP/C: good response; serially increasing plasma creatinine concentration and/or increasing UP/C: disease progressing.

‡Aluminium hydroxide, aluminium carbonate, calcium carbonate, calcium acetate dosed to effect (starting at 30-60 mg/kg with each feeding mixed with the food if possible). The dose required varies according to the amount of phosphate being fed and the stage of CKD.

Management of Dehydration

At all stages of CKD patients have decreased urine concentrating ability and therefore one should correct clinical dehydration with isotonic, polyionic replacement fluids **and** have fresh water available at all times.

Management of Hypertension*

Hypertension can occur at any stage of CKD. Recommended treatments and monitoring are the same regardless of stage (Table 192-5). The goal is to reduce systolic blood pressure (SBP) to <160 mm Hg, minimizing risk of extrarenal end organ damage (e.g., CNS, retinal, cardiac)[†]. If evidence of such damage is lacking but SBP persistently exceeds 160 mm Hg, treatment should be instituted. *Persistence* should be judged on multiple SBP measurements made over 2 months (if at low to moderate risk [i.e., 150 to 179 mm Hg SBP]) or over 1 to 2 weeks (if at severe risk [i.e., ≥180 mm Hg]). Animals with end organ damage should be treated without the need to demonstrate persistence. Reducing blood pressure is a long-term treatment aim; gradual and sustained reduction should be the goal, avoiding sudden/severe decreases leading to hypotension. The recommended approach differs slightly in the dog and cat. In both species there is limited evidence that lowering dietary sodium alone is beneficial, but if attempted as part of a treatment protocol it should be done gradually (Table 192-4).

Lifelong antihypertensive therapy is usually required, and serial SBP monitoring is essential. After stabilization, monitoring every 3 months is the minimum. SBP <120 mm Hg and/or weakness/tachycardia indicate hypotension, which is to be avoided. Reducing blood pressure may lead to small and persistent increases in creatinine (<0.5 mg/dl), usually within 5 to 7 days of adjusting treatment. Marked acute increases in creatinine suggest an adverse drug effect, whereas gradual increases indicate deteriorating kidney function.

Other Management Procedures

Other aspects of management are summarized in Table 192-4. Specific dose rates are not stipulated. Standard dose rates apply for starting therapy with most agents, although caution is advisable with drugs eliminated mainly by renal mechanisms. Most complications of CKD, at which therapy is directed, become more prevalent with severity of CKD. In contrast, proteinuria and systemic hypertension can occur at any stage. They are integral to substaging because they are targets for therapy at all stages and are considered risk factors for CKD progression.

Diet can be manipulated to achieve multiple management goals in CKD. Each is dealt with in Table 192-4.

* These recommendations are based on systolic blood pressures. Corresponding diastolic pressures presented in Table 192-3 can also be used to aid treatment decisions.

[†] The target posttreatment blood pressure necessary to prevent hypertensive renal damage is currently unknown.

Table 192-5

A Logical Stepwise Approach to Managing Canine and Feline Hypertension

Step	Canine	Feline
1	ACEI therapy at the standard dose	Administer a CCB (generally amlodipine besylate)
2	Double dose of ACEI (improves antihypertensive effect in some patients)	Increase the dose of amlodipine up to 0.5 mg/kg/day
3	Combined treatment with an ACEI and a long-acting calcium channel blocker (CCB, generally amlodipine besylate)	Combined treatment with CCB and an ACEI
4	Combined treatment with ACEI, CCB and hydralazine	

Thus, dietary management often addresses several therapeutic targets including the following:

- Hyperphosphatemia and hyperparathyroidism: Limiting the dietary phosphate is beneficial in dogs and cats with CKD
- Proteinuria: Supplementing n-3 PUFAs and restricting protein intake address this problem
- Hypertension: Many commercial diets formulated for CKD patients have restricted sodium content (see above)
- Hypokalemia: Commercial diets formulated for feline CKD patients often have increased potassium content, but additional potassium may be required
- Azotemia: In the later stages of CKD, restriction of protein intake can reduce nitrogenous waste products within the blood.

The stage at which each therapeutic strategy is appropriate varies (see Table 192-4). The need for frequent monitoring and adjustment of therapy is an important principle here.

SUMMARY

The IRIS staging system reflects current knowledge and opinion about CKD in dogs and cats and will continue to evolve. Consistent, widespread use of such staging should help practitioners with diagnosis and prognosis in CKD, provide a framework for formulating treatment plans, and facilitate communication within the veterinary community.

ACKNOWLEDGMENT

The work of the IRIS Group is facilitated by generous funding from Novartis Animal Health. Updates can be accessed at <http://www.iris-kidney.com>.

CHAPTER 193

Calcitriol

DAVID J. POLZIN, *St. Paul, Minnesota*
SHERI ROSS, *San Diego, California*
CARL A. OSBORNE, *St. Paul, Minnesota*

OVERVIEW OF CALCIUM AND PHOSPHORUS METABOLISM

Precise control of both phosphate and calcium homeostasis is essential to the normal functioning of virtually all life-sustaining physiologic processes. Disturbances in metabolism of the divalent ions calcium and phosphorus are common in patients with chronic kidney disease (CKD). Typical abnormalities seen in patients with CKD include hyperphosphatemia, hypocalcemia, hypercalcemia, renal secondary hyperparathyroidism, and calcitriol deficiency. Because these disturbances have been linked to increased morbidity and mortality in CKD, therapeutic intervention directed at minimizing these abnormalities and their systemic effects is an important component of conservative medical management of CKD.

The principal components involved in divalent ion metabolism that are relevant to patients with CKD include calcium, phosphorus, parathyroid hormone (PTH), and calcitriol. The primary goal of this system seemingly is to maintain normal blood calcium concentrations. Although calcium occurs in ionized, complexed, and protein-bound forms in blood, ionized calcium concentration is the primary component monitored and regulated. A reduction in blood ionized calcium concentration stimulates secretion of PTH. The amount of pre-

formed PTH present in parathyroid cells is limited, and PTH degrades rapidly. Hypocalcemia increases PTH secretion by a posttranscriptional mechanism acting through the parathyroid gland membrane calcium-sensing receptor to stabilize PTH messenger ribonucleic acid. Increased PTH secretion acts to restore ionized calcium levels by three mechanisms: (1) increasing renal calcium resorption from the ascending loop of Henle, distal tubule, and collecting tubule; (2) increasing calcium resorption from bone; and (3) enhancing formation of calcitriol (1,25-dihydroxycholecalciferol) from 25-hydroxycholecalciferol by the kidneys. Calcitriol promotes elevation of serum calcium levels by enhancing absorption of calcium from the intestines and facilitating the effect of PTH on bone. The resulting increase in serum calcium levels reduces secretion of PTH. In addition, through a mechanism independent of blood calcium concentration, increased calcitriol levels inhibit synthesis and storage of PTH by activating vitamin D receptors (VDR), resulting in decreased PTH gene transcription.

Serum phosphate levels reflect the balance between intestinal absorption and renal excretion of phosphate. Intestinal absorption of phosphate is a function of: (1) dietary phosphorus content, (2) the amount of phosphate rendered insoluble by formation of nonabsorbable phosphate complexes within the intestinal lumen

(e.g., calcium phosphate), and (3) the action of calcitriol to enhance intestinal phosphate absorption. Serum phosphate levels influence intestinal calcium and phosphorus absorption through an effect on renal calcitriol production. Phosphate retention and hyperphosphatemia inhibit renal 1- α hydroxylase activity, the enzyme responsible for renal conversion of 25-hydroxycholecalciferol to calcitriol, the most active form of vitamin D. By decreasing calcitriol levels, phosphate retention and hyperphosphatemia reduce intestinal phosphate absorption. In contrast, hypophosphatemia may be associated with elevated calcitriol levels, leading to increased intestinal absorption of phosphate. Renal phosphate excretion results from a combination of glomerular filtration and proximal tubular resorption. If phosphate intake remains unchanged, reduced glomerular filtration rate consistently increases retention of phosphate and promotes hyperphosphatemia. As described previously, hyperphosphatemia promotes elevated PTH activity. This increase in PTH activity is appropriate because PTH blocks proximal renal tubular resorption of phosphate, thus promoting phosphaturia, which facilitates restoration of normal serum phosphate concentrations.

PATHOPHYSIOLOGY OF RENAL SECONDARY HYPERPARATHYROIDISM

The inciting event in development of renal secondary hyperparathyroidism is retention of phosphate caused by reduced renal excretion (Fig. 193-1). Phosphate retention stimulates increased PTH production and secretion both by a direct effect of phosphate on the parathyroid gland and by reducing renal production of calcitriol by inhibiting renal 1- α hydroxylase activity. Hyperphosphatemia

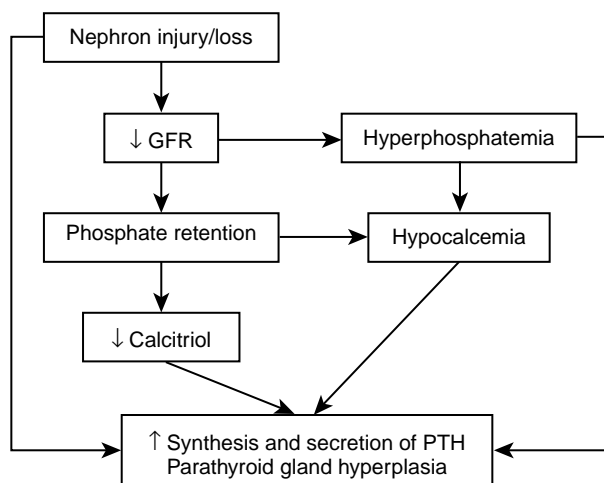

Fig. 193-1 Mechanism of development of renal secondary hyperparathyroidism. Reduced glomerular filtration rate initiates development of hyperparathyroidism by promoting phosphate retention and hyperphosphatemia. Phosphate retention suppresses the renal enzyme 1- α hydroxylase, which catalyzes the conversion of 25-hydroxycholecalciferol to 1,25-dihydroxycholecalciferol or calcitriol, the most active form of vitamin D. Calcitriol deficiency, hypocalcemia, and hyperphosphatemia all potentially contribute to development of hyperparathyroidism and parathyroid gland hyperplasia.

may also promote PTH secretion by complexing with ionized calcium, thereby lowering ionized calcium concentration. Elevated PTH levels increase phosphaturia, thereby maintaining serum phosphate within normal limits. Thus, at least initially, secondary hyperparathyroidism and its consequences are the long-term “trade-off” for the short-term benefit of maintaining normal serum phosphate concentrations. However, as renal disease progresses, the capacity to increase phosphaturia becomes insufficient to prevent hyperphosphatemia. In addition, loss of nephrons progresses to the point at which insufficient renal mass remains to sustain adequate production of calcitriol.

Persistent calcitriol deficiency may lead to parathyroid gland hyperplasia and hypertrophy with sustained autonomous secretion of PTH, a condition often referred to as *tertiary hyperparathyroidism*. Tertiary hyperparathyroidism typically is resistant to conventional medical interventions, and surgical reduction in the renal mass may be required to normalize PTH levels. Maintaining adequate levels of calcitriol throughout the course of CKD is important in preventing development of tertiary hyperparathyroidism because calcitriol has antiproliferative properties, decreases PTH gene transcription, and represses parathyroid cell proliferation.

RECOMMENDATIONS FOR USE OF CALCITRIOL IN CHRONIC KIDNEY DISEASE

Managing Divalent Ion Disorders in Chronic Kidney Disease

Minimizing development of calcium and phosphate disturbances and their consequences is a critical component of therapy for patients with CKD. The goals of management of divalent ion disturbances and renal secondary hyperparathyroidism in CKD are to: (1) reduce hyperphosphatemia and the mechanisms underlying phosphate retention; (2) restore adequate levels of active vitamin D (calcitriol), and (3) normalize serum calcium concentrations.

Therapy should begin by introducing a reduced phosphorus diet. The goal is to reduce serum phosphate concentration below 6mg/dl (ideally, serum phosphate concentration should probably be in the range of 4.5 to 5.5mg/dl). Diets designed for patients with CKD are appropriate for this purpose in that phosphorus content is typically reduced by 75% or more compared to typical maintenance-type diets. This dietary modification normalizes serum phosphate concentrations and reduces or normalizes PTH levels in most patients with CKD stage II and many patients with CKD stage III. Diet alone is unlikely to be sufficient therapy for patients with CKD stage IV (see Chapter 192).

When diet therapy alone fails to normalize serum phosphate concentrations and/or PTH levels, uptake of phosphorus can be further reduced by addition of an intestinal phosphate binding agent. Intestinal phosphate binding agents typically release cations (e.g., aluminum, calcium, or lanthanum), which bind irreversibly to phosphate in the intestinal lumen, thus rendering bound

phosphate nonabsorbable. However, a potential disadvantage of intestinal phosphate binders is that some of the cations released may be absorbed and produce adverse effects. For example, aluminum retention has been associated with adverse hematologic, skeletal, and nervous system effects; and calcium-based binders may promote hypercalcemia. One product, sevelamer hydrochloride (Renagel, Genzyme Corp.) is a polyhydrochloride polymer that does not release cationic metals; however, it is very expensive and appears to be no more effective than less expensive binding agents.

The initial dosage of aluminum or calcium-based phosphate binders is 30 to 90 mg/kg/day given orally with food. It is important to administer the phosphate binder with food because the goal of this therapy is to bind the phosphorus contained in food so that it is not absorbed. Administering phosphate binders between meals is likely to markedly reduce the effectiveness of phosphate binding while promoting absorption of the cation contained in the binder. The dose of phosphate binding agent should be adjusted to achieve the goal of reducing serum phosphate concentration to below 6 mg/dl. In general, use of calcium-based phosphate binding agents is not recommended for patients receiving calcitriol. The exception to this rule may be in patients with overt hypocalcemia.

Once serum phosphorus has been reduced to below 6 mg/dl, calcitriol therapy may be initiated. Because calcitriol promotes intestinal absorption of both calcium and phosphorus, failure to adequately control serum phosphate concentration before initiating calcitriol may result in hyperphosphatemia, elevation in the serum calcium \times phosphate product, and soft-tissue mineralization.

Benefits of Calcitriol Therapy

A host of clinical benefits have been hypothesized to accrue from calcitriol therapy in dogs and cats with CKD, including enhanced survival, appetite, activity, alertness, and interactivity with owners. It is common to use calcitriol in management of renal osteodystrophy in humans, but clinical signs of this condition are less prominent in most dogs and cats with CKD. The most important proposed benefit of calcitriol therapy, prolonged survival, has been confirmed in dogs with stages III and IV CKD (Polzin et al., 2005b) but remains unproven in cats with CKD. Evidence supporting the other clinical benefits of calcitriol is limited to pathophysiologic justification and clinical observations. Randomized clinical trials have failed to confirm that calcitriol ameliorates clinical signs in dogs and cats with CKD, but these studies were performed in stable CKD patients that were not exhibiting overt signs or anorexia, lethargy, or depression. Serum phosphate concentrations were aggressively managed in these studies; thus the magnitude of hyperparathyroidism was limited in both control and calcitriol groups. As a consequence, the hypothesized benefits of calcitriol on appetite, activity, and alertness may not have been observed. The fact that calcitriol forestalled onset of clinical signs of uremia in dogs may be interpreted as evidence of limiting development of the adverse clinical signs associated

with uremia. Further clinical trials will be necessary to validate whether calcitriol ameliorates clinical signs associated with CKD.

Although the beneficial effects of calcitriol have traditionally been ascribed to suppression of PTH, this may not be the only mechanism of action of calcitriol. Recent epidemiologic studies in humans have suggested an important systemic role for direct activation of the VDR. Emerging data suggest that vitamin D therapy may prolong survival by mechanisms independent of calcium, phosphorus, and PTH. In canine studies demonstrating a beneficial effect of calcitriol on survival, differences in serum phosphorus, calcium, and PTH levels between the calcitriol group and placebo group were small. Further, studies in humans have shown that paricalcitol, a selective activator of the VDR, is associated with a more favorable efficacy to side-effect profile than calcitriol, with less morbidity and better survival.

Indications for Calcitriol

Dogs With Chronic Kidney Disease

In a randomized controlled clinical trial, calcitriol was shown to prolong survival and forestall development of uremic crises in dogs with stage III and early stage IV CKD. Because the rate of progression of CKD was slower in dogs receiving calcitriol in this study, it was concluded that calcitriol favorably influenced clinical outcome as a consequence of providing a renoprotective effect. These findings are consistent with observations in humans with CKD. On the basis of these findings, calcitriol therapy is indicated for dogs with stage III and early stage IV CKD. Calcitriol therapy is indicated in these patients even if PTH levels are not elevated. Because advanced hyperparathyroidism may be difficult or impossible to manage medically, early intervention or prophylaxis is recommended. However, the value of calcitriol therapy in dogs with stages I and II CKD has not been established.

Cats With Chronic Kidney Disease

There are insufficient data on which to base a recommendation for or against calcitriol administration to cats with any stage CKD. A 1-year-duration randomized, controlled clinical trial in our hospital failed to confirm any clinical benefits for cats in stages II, III, and IV CKD; but the possibility that calcitriol is of benefit was not excluded by this study.

Dosing Calcitriol

Baseline values for serum calcium (ideally ionized calcium) concentration, phosphorus concentration, and PTH activity should be established before beginning calcitriol therapy and then repeated after 2 to 4 weeks of therapy. We recommend starting calcitriol at a dosage of 2.5 ng/kg orally once daily. Calcitriol dosage should be adjusted so that PTH levels are reduced into the normal range without inducing hypercalcemia. If PTH remains elevated after 2 to 4 weeks of therapy, calcitriol dose may be increased to 3.5 ng/kg. Calcium and PTH levels should be reassessed after an additional 2 to 4 weeks; and if PTH remains elevated, calcitriol dose may be increased cautiously to 4.5

to 5 ng/kg. At this level monitoring serum calcium concentration becomes even more essential. We do not recommend increasing daily calcitriol dosage above 5 ng/kg/day. We have found that, in most dogs and cats in stages II and III CKD, doses between 1.5 and 5 ng/kg are effective in normalizing PTH activities. Effectiveness of calcitriol therapy at relatively low doses is not surprising given that a near maximal effect of calcitriol on PTH gene transcription occurs at or near physiologic levels. However, the effectiveness of calcitriol in lowering PTH levels may be impaired by overt hypocalcemia. In such instances it may be necessary to cautiously provide oral calcium supplementation. Long-standing hyperparathyroidism with parathyroid hyperplasia may be associated with a deficiency of VDR on the hyperplastic parathyroid cells, resulting in hyperparathyroidism that is refractory to calcitriol therapy. Since calcitriol induces formation of the VDR on parathyroid cells, long-standing deficiency of calcitriol may contribute to the deficiency of VDR in this setting. In such instances a more prolonged course of calcitriol therapy or "pulse" therapy (see following paragraphs) may be attempted to determine if PTH levels can be reduced.

Should calcitriol therapy induce an increase in ionized calcium concentration, it may be necessary to reduce calcitriol dosage. Calcitriol-induced hypercalcemia may also be ameliorated by administering calcitriol in the evening on an empty stomach when calcitriol is less likely to promote enhanced intestinal calcium absorption. If hypercalcemia persists, pulse dosing may be considered.

Pulse therapy involves administration of larger doses of calcitriol at less frequent intervals. Pulse therapy may induce formation of greater numbers of VDR on parathyroid cells, rendering the gland more responsive to the action of calcitriol. In addition, pulse therapy may minimize the tendency for calcitriol therapy to induce hypercalcemia since it induces hypercalcemia by promoting intestinal absorption of calcium. Calcitriol promotes intestinal absorption of calcium through its effect on newly formed intestinal cells leaving the crypts of Lieberkühn. The tendency of these cells to absorb calcium is determined largely by their exposure to calcitriol only during this early developmental phase. Since calcitriol has a relatively short half-life (about 4 to 6 hours), less frequent administration limits the number of intestinal cells primed to enhanced calcium absorption, thereby moderating the predisposition of calcitriol to induce hyperabsorptive hypercalcemia. Pulse therapy is usually provided at twice the usual daily dose (for a total dose of 5 to 10 ng/kg) administered orally every other day. Once hyperparathyroidism is controlled using pulse therapy, an attempt should be made to revert to daily low-dose administration of calcitriol.

Calcitriol must be compounded into a dose size appropriate for dogs and cats. It is important to remember that the quantity of calcitriol contained in capsules designed for use in humans contains a considerable overdose when administered to dogs and cats; this quantity should never be used in these species.

Potential Complications of Calcitriol Therapy

In our studies we found low-dose calcitriol therapy to be quite safe. No obvious adverse effects were noted, although calcitriol doses occasionally had to be reduced because of development of hypercalcemia. Hyperphosphatemia, hypercalcemia, and elevated calcium x phosphate product are relative contraindications to calcitriol therapy. Development of hypercalcemia and soft-tissue mineralization, particularly of the vascular system, is of great concern in humans with CKD. Because of the tendency for calcitriol to promote hypercalcemia, selective VDR activators such as paricalcitol (Zemlar) and doxercalciferol have been developed. In humans with CKD these compounds appear to provide adequate control of hyperparathyroidism with minimal changes in serum calcium and phosphate concentrations, even when calcium-based intestinal phosphate binding agents are used. As mentioned previously, these compounds appear to have less morbidity and mortality associated with their use compared to calcitriol. However, the long-term benefits of these compounds remain to be established. There are no reports on the use of paricalcitol in dogs or cats with spontaneous CKD.

Monitoring Patients With Calcitriol

Although low-dose calcitriol appears to generally be safe, monitoring is advocated to optimize therapy and avoid iatrogenic complications. Ideally serum calcium, ionized calcium, phosphate, and PTH levels should be evaluated every 2 to 4 weeks until the desired dosage is established. Thereafter these parameters and serum creatinine concentration should be monitored every 3 to 6 months; however, the frequency of monitoring should be individualized to each patient based on response to therapy and stability of the monitored values. The goal of therapy is to maintain serum phosphate, calcium, and PTH levels within normal limits.

Hemodialysis

CATHERINE E. LANGSTON, *New York, New York*

The most common application of hemodialysis is therapy of renal failure that is not responsive to medical management. Hemodialysis also can be used for the removal of ingested toxins (e.g., ethylene glycol), selected drug overdoses, and volume overload. Dialysis modalities, including intermittent hemodialysis (IHD) and continuous renal replacement therapy (CRRT), are becoming more readily available, and Internet-savvy clients are requesting referral for these therapies for their pets. This chapter covers the information of importance to practicing veterinarians regarding hemodialysis and highlights some of the exciting developments in this field.

PRINCIPLES OF DIALYSIS

Hemodialysis removes uremic toxins from the bloodstream by diffusion. During the treatment a continuous flow of blood from the patient is carried to the dialyzer through disposable tubing (extracorporeal circuit, Fig. 194-1). The dialyzer, or artificial kidney, contains a porous membrane. As with the kidney, size and charge are major determinants determining which particles are filtered by the dialyzer. Small to middle-sized molecules in high concentration in the bloodstream, such as urea and creatinine, diffuse through the pores into a dialysate solution on the opposite side of the membrane. Large molecules such as albumin and cells are too large to pass through the pores and remain in the bloodstream. Because necessary electrolytes such as sodium can pass through the membrane easily, the dialysate solution has physiologic concentrations of these electrolytes, preventing significant loss from the patient. After passing through the dialyzer, the blood is returned to the patient. In a standard 4- to 5-hour intermittent dialysis treatment, a patient's blood volume may be circulated through the machine the equivalent of 20 to 30 times. Ultrafiltration removes fluid from the patient by creating a hydrostatic pressure gradient between the blood compartment and the dialysate compartment.

DIALYSIS EQUIPMENT

Dialysis Machines

There are a variety of models and manufacturers of dialysis machines, but all must circulate blood in the extracorporeal circuit, circulate dialysate, and precisely control ultrafiltration. Most machines also have an integrated syringe pump to deliver a constant infusion of heparin or other anticoagulant during the treatment.

Intermittent hemodialysis generally involves rapid blood and dialysate flow for efficient removal of uremic

toxins and fluid, allowing treatments to occur at intervals. A typical regimen would include several hours per treatment, three to four times per week. Machines designed for IHD are capable of supplying the large volume of dialysate necessary by mixing purified water with concentrated electrolyte solutions. Sodium and bicarbonate concentrations can be adjusted independently and tailored to the patient's needs. The resulting dialysate is purified but not sterile; thus low levels of endotoxins may contribute to chronic inflammation in IHD patients. Newer IHD machines include an additional filtration step in dialysate delivery, creating what is termed *ultrapure* dialysate. IHD machines require a water treatment system, which may be a large-capacity system that pipes water to the dialysis unit or a contained water treatment system that can supply purified water for a single machine. These machines can be programmed to perform at a wide variety of blood flow rates to allow for variability of patient size and can provide a high or low efficiency treatment. Because of the complexity of equipment and the possibility of acute changes in patient status during treatment, IHD is usually performed by specially trained dialysis personnel.

CRRT uses the same general principles as IHD, with the exception of timing. CRRT is intended to be a continuous dialysis treatment, which is sustained until renal recovery occurs or until the patient is stable and can be transitioned to IHD. CRRT machines do not create dialysate, and prepackaged sterile dialysate is used with these machines. Dialysate flow rates are much slower with CRRT (up to 6 L/hour) compared to IHD (20 to 50 L/hour). In many human facilities, CRRT is instituted by the dialysis personnel, who are available for machine preparation and scheduled dialyzer and tubing changes (manufacturer's recommendation is to change materials every 3 days). The patient and machine are then monitored around the clock by CRRT-trained intensive care unit nursing staff. A dialysis team member is usually available (either by phone or on call) for troubleshooting. Common problems with CRRT include poor blood flow (usually caused by catheter size or malposition) and excessive clotting in the dialyzer, necessitating unscheduled changes of the extracorporeal circuit. "Hybrid" machines that can perform either modality recently have become available, allowing low-efficiency continual therapy initially until the patient is more hemodynamically stable and then more aggressive intermittent treatments as needed.

Monitoring Devices

Careful monitoring of the dialysis patient is necessary. Some of the parameters that require close monitoring during treatment include blood pressure, coagulation status,

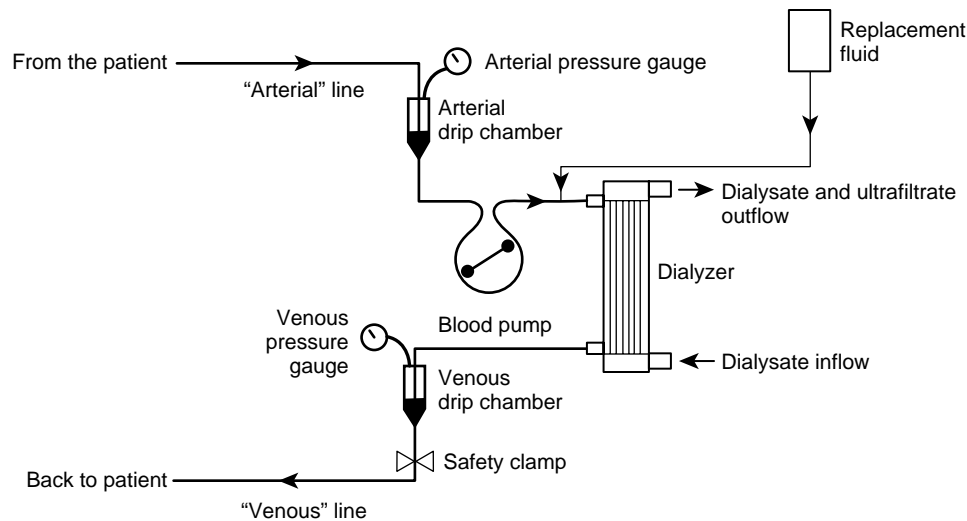

Fig. 194-1 Pathway of blood from the vascular access in the patient through the extracorporeal circuit and back to the patient.

and blood volume. Indirect blood pressure measurement can be accomplished with a variety of devices. Typically during treatment blood pressure is monitored every 15 to 30 minutes for IHD, and slightly less frequently in a stable patient on CRRT. Rapid assessment of coagulation parameters is necessary to adjust anticoagulant dosing during treatment (see section on Anticoagulation later in the chapter). Multiple devices are available specifically for monitoring dialysis patients, and newer dialysis machines incorporate these technologies into the system design. A hemoglobin sensor placed on the blood tubing can continuously determine the hematocrit and is used to determine relative blood volume changes, working under the presumption that red blood cells are neither being added nor removed from the patient during the treatment. Hematocrit will change related to plasma volume expansion (decreased hematocrit) or contraction (increased hematocrit). Rapid ultrafiltration can remove volume from the intravascular compartment faster than it can refill from the interstitium, and this situation can lead to symptomatic hypotensive episodes during dialysis. Close monitoring of the relative blood volume should minimize the likelihood of a hypotensive event.

Vascular Access

Both IHD and CRRT require vascular access. Depending on the predicted duration of dialysis treatments, the dialysis nephrologist may choose to select a catheter for short-term (temporary) or long-term (permanent) use. For short-term treatment double-lumen catheters placed percutaneously with a guidewire (Seldinger technique) or via minor surgical exposure of the vessel are the most commonly used type of vascular access. These catheters can be placed with a local anesthetic and mild sedation. Regardless of the anticipated treatment duration, generally the largest feasible catheter size is selected to ensure sufficient blood flow (up to 20ml/kg/minute for IHD) for an efficient dialysis treatment. An 11.5-Fr dual-lumen hemodialysis catheter (MedComp) can be placed in most medium-to-large dogs and provides up to 350ml/minute

blood flow; these catheters can be maintained for 4 weeks or longer. In cats a 7-Fr dual-lumen central catheter (Arrow International) can be placed percutaneously. The 7-Fr catheter accommodates up to 100ml/min blood flow in in vitro experiments; however, in clinical use these catheters frequently do not provide sufficient blood flow for medium- to high-efficiency treatments. Smaller catheters such as a 5.5-Fr double- or triple-lumen catheter can be placed in smaller cats and provide 5- to 10-ml/minute blood flow, which would be appropriate for early IHD (low efficiency regimens) and potentially for CRRT.

Long-term dialysis catheters are placed surgically, leaving the proximal portion of the catheter in a subcutaneous tunnel. The tunnel separates the skin exit site from the venotomy site, decreasing infectious complications, and a Dacron cuff helps anchor the catheter in place. These catheters have remained functional for 6 to 9 months in dogs. New catheter designs, including separation of the two catheter lumens in the same vessel, have helped decrease catheter malfunction from thrombus formation in and around the catheter.

For chronic dialysis a subcutaneous graft or fistula is the most common method of access in humans but must be surgically created at least a month before use. A model of surgically created grafts has been developed in dogs but is not in widespread use.

ANTICOAGULATION

Some form of anticoagulation is needed during dialysis to prevent thrombosis in the extracorporeal circuit. Unfractionated heparin is the most commonly used anticoagulant. Activated clotting time (ACT) has traditionally been monitored during treatment, and the results have been used to adjust the heparin dose, with a goal of maintaining the ACT at 1.6 to 2 times normal. Excessive clotting and bleeding are potential complications of heparin anticoagulation. Low-molecular weight heparin is not commonly used in veterinary hemodialysis, and its use in human hemodialysis generally is limited to high-risk patients because of the high cost

compared with unfractionated heparin. With advances in technology, use of bedside monitors that can accurately measure partial thromboplastin time with a small volume of blood may replace ACT monitoring in the future of veterinary hemodialysis.

Regional citrate anticoagulation is used in some human and veterinary CRRT units. Citrate, administered as a constant-rate infusion into the extracorporeal circuit, binds calcium, preventing coagulation in the circuit. Since the anticoagulation occurs outside of the patient, bleeding complications associated with anticoagulation are minimized. Calcium chloride is administered through a centrally placed intravenous catheter or via the extracorporeal circuit just at the point where the blood is reentering the body to avoid hypocalcemia in the patient. This procedure is complex and requires frequent blood calcium monitoring and dose adjustments of both citrate and calcium infusions, but it diminishes the risk of hemorrhage associated with long-term heparinization. Citrate is relatively contraindicated in the face of hepatic dysfunction.

INDICATIONS FOR DIALYSIS

IHD and CRRT are most commonly used to treat acute renal failure (ARF). The goal of acute dialysis is to resolve life-threatening disorders (i.e., hyperkalemia, pulmonary edema) and control uremia, thus decreasing subsequent uremic complications, allowing time for renal repair to occur. In contrast, chronic dialysis is used to control signs associated with end-stage renal failure for the remainder of the patient's life.

Dialysis is appropriate for any disease causing ARF. Common reasons for acute dialysis include leptospirosis, bacterial pyelonephritis, toxic nephropathy (e.g., ethylene glycol, lily ingestion, grapes/raisins, aminoglycosides), and renal ischemia. Dialysis can also be used in patients with acute uremia syndrome associated with ureteral obstruction. Dialysis is being used to manage these patients before surgery, allowing control of hyperkalemia and other life-threatening uremic complications, allowing time for diagnostic evaluation, and improving patient stability in preparation for anesthesia. Generally one to three treatments before surgery are adequate. Two to four dialysis treatments before renal transplantation surgery have also been used in some institutions to stabilize patients with acute uremic crisis or severe uremia (Cowgill and Francey, 2006).

Client demand for chronic hemodialysis for chronic kidney disease (CKD) is increasing. Because of the irreversible nature of CKD, dialytic treatment is ongoing, typically three treatments a week; treated patients can maintain an excellent quality of life for extended periods of time (6 to 12 months or more).

Certain drugs and toxins can be removed with dialysis. Substances with low-molecular weight and minimal protein binding are more readily removed. Rapid removal of the offending substance is generally desired. With IHD a charcoal perfusion cartridge can be placed in series with the dialyzer, expanding the possible toxicities that can be treated. In contrast to dialytic removal, charcoal perfusion involves filtering the blood across microencapsulated charcoal beads, which adsorb the toxic compound, removing it from the circulation. Because medications

given for therapeutic purposes also can be removed by dialysis, dose alterations may be necessary in patients receiving dialysis.

Slow continuous ultrafiltration (removal of fluid from the patient) without concurrent dialysis can be used to treat volume overload situations that are not associated with renal failure (i.e., diuretic-resistant congestive heart failure). Therapeutic plasmapheresis can also be performed, using a plasmapheresis cartridge instead of a dialyzer, although appropriate indications for plasmapheresis are not well established. Plasmapheresis differs from dialysis in that large pores in the cartridge allow removal of albumin and globulins, separating the plasma from the cellular components. There is little veterinary experience with either of these techniques.

INITIATING DIALYSIS

Anuria or oliguria that does not respond to volume expansion and diuretics is a clear indication for starting dialysis. Volume overload, which may manifest as life-threatening pulmonary edema or pleural effusion, can occur with oliguria or anuria or in patients with an inappropriate urine output relative to the volume of administered fluid; they are both indications for dialysis. Hyperkalemia is an immediately life-threatening complication. Medical strategies for hyperkalemia (i.e., insulin, dextrose, bicarbonate, or calcium) can be used as temporary measures but do not remove the excess potassium from the body (see Chapter 191). IHD can remove potassium rapidly and minimize cardiac toxicity, normalizing the electrocardiogram. Severe uremia (blood urea nitrogen >100mg/dl, creatinine >10mg/dl) and uremia that does not respond to the first 24 hours of medical management are other indications for dialysis (Box 194-1). In humans instituting dialysis earlier in the course of renal failure improves outcome and the likelihood of return of renal function; early referral for dialysis, before the onset of severe extrarenal manifestations of uremia, is prudent in the veterinary field also (Box 194-2).

The decision to start dialysis for CKD generally is based on failure of medical management to control signs of uremia such as anorexia, lethargy, or vomiting. Frequently a feeding tube is placed at the time of dialysis catheter placement in these patients to provide nutritional support

Box 194-1

Indications for Hemodialysis

- Oliguria or anuria unresponsive to therapy
- Volume overload
- Hyperkalemia
- Severe uremia (blood urea nitrogen >100mg/dl, creatinine >10mg/dl)
- Uremia unresponsive to medical management for 24 hours
- Poisoning or drug overdose (ethylene glycol, aspirin, acetaminophen, phenylbutazone, digoxin, amikacin, azathioprine, cyclophosphamide, enalapril, procainamide, phenobarbital, theophylline, many others)

during the initial few weeks of dialysis and during periods of stress. Dialysis for toxin removal should be instituted as rapidly as possible. Patients with antifreeze ingestion should receive a dose of 4-methylpyrazole (dogs) or ethanol (cats) to slow metabolism of ethylene glycol while arrangements for dialysis are being made.

TREATMENT PROTOCOLS

IHD is an efficient method of solute removal and an appropriate treatment modality for ARF, CKD, acute toxicities, and fluid removal. With severe azotemia rapid reduction of urea can lead to untoward effects; thus the first few IHD treatments are abbreviated. Several (usually three to seven) short daily treatments are applied to gradually control metabolic derangements associated with severe uremia. Ongoing treatments, typically of 4- to 5-hour duration three times a week, are performed until the patient has regained renal function. Some patients can be discharged from the hospital after the first 2 weeks of treatment and return for outpatient dialysis treatments over the next several weeks. With severe uremia in an unstable patient, the first treatment may be long (6 to >24 hours) with slow blood flow to gradually control the uremic manifestations while diminishing risk of complications, a prescription referred to as slow low-efficiency dialysis.

CRRT is an appropriate treatment modality for ARF and fluid removal and is usually applied for a short-term duration. CRRT treatments in human pediatric patients have a mean duration of about 4 days (range 0.5 to 30 days). CRRT typically is started with a modest blood flow rate (2 to 3 ml/kg/minute compared to 5 to 20 ml/kg/minute with IHD) and slow dialysate flow rate (8 to 34 ml/minute compared to 500 ml/minute with IHD). The clinician determines the desired net fluid removal rate based on patient hydration status. Additional ultrafiltration with fluid replacement to enhance convective solute clearance (removal of solutes dissolved in the fluid that is removed from the patient) ranges from 0 to 35 ml/kg/hour. Once treatment is started, these parameters may be adjusted to achieve the desired clearance. Clinical indicators of recovery (e.g., increase in urine output) may prompt the clinician to decrease the blood or dialysate flow rate in attempt to wean the patient off CRRT.

COMPLICATIONS

Complications encountered during dialytic management may be a result of the dialysis procedure or of the underlying renal failure.

Procedural Complications

Dialysis disequilibrium syndrome is a condition characterized by a rapid decline in blood osmolality caused by removal of osmoles (especially urea) by dialysis. Because the osmoles can be removed from the blood faster than they can diffuse from the intracellular compartment, a state of relative intracellular hyperosmolality ensues. Subsequent cellular swelling leads to central nervous system signs (i.e., seizures, mentation changes). Patients

at increased risk for dialysis disequilibrium syndrome include those with severe azotemia, smaller blood volumes, or preexisting neurologic signs. Slow, low-efficiency dialysis or CRRT can be used to reduce the likelihood of this complication, as can prophylactic administration of the osmotic agent mannitol.

In small patients removal of the blood volume necessary to fill the dialysis circuit can result in hypotension. In an effort to minimize this complication, colloidal substances (e.g., dextran) may be used to prime the circuit. Administration of colloids or blood products may be required to maintain blood pressure throughout treatment. Ultrafiltration can also cause significant hypovolemia. Temporarily stopping ultrafiltration may be sufficient to manage a hypotensive event.

Hemorrhage related to heparin anticoagulation is most likely during the first few dialysis treatments, while the individual response to heparin is being determined, and with prolonged sessions (>6 hours). Thrombosis at the tip of the dialysis catheter in the right atrium is common with catheters in place for over 3 weeks and impairs adequate blood flow. Clinically significant pulmonary thromboembolism is uncommon, but vena caval thrombosis or stenosis (with intermandibular edema) is a well-recognized complication in dogs. Early treatment of complete or partial catheter occlusion with human recombinant tissue plasminogen activator (alteplase, Cathflo Activase, Genetech) may salvage a malfunctioning catheter.

The tips of a dual-lumen hemodialysis catheter are staggered. The more proximal tip removes blood from the patient to carry it to the dialyzer. Blood coming from the dialyzer, which has been cleared of uremic toxins, is returned through the distal tip and swept forward in the bloodstream. A poorly functioning catheter may create turbulence and pressure gradients that allow uptake of the returning dialyzed blood, decreasing the efficiency of solute clearance. The amount of recirculation can be measured by a variety of methods to determine if intervention is indicated.

Uremic Complications

Manifestations of uremia (e.g., oral, gastrointestinal) are common in ARF patients. With dialytic management survival can be enhanced such that a variety of less common uremic complications are also observed. Respiratory dysfunction, presumptively from pulmonary edema or uremic pneumonitis, is encountered frequently. Pulmonary hemorrhage associated with leptospirosis is another cause of respiratory compromise. Interestingly, a frequent uremic complication in patients on dialysis for ARF is moderate-to-severe fulminant pancreatitis, although it may not be detected antemortem. Common clinical signs of pancreatitis (anorexia, vomiting, abdominal pain) overlap with signs of ARF; when these signs persist despite adequate control of uremia by dialysis, careful evaluation for pancreatitis is warranted.

OUTCOME

Overall 40% to 60% of patients with ARF treated with dialysis survive, a notable achievement given that the patient

population is comprised of animals unresponsive to conventional medical management (Langston, 2003). However, there are marked differences in survival for different etiologies of ARF. The survival rate for ARF from infectious causes was about 60% to 70% (Francey and Cowgill, 2002; Francey, 2004). Hemodynamic and metabolic causes had a 40% to 56% survival rate. Only 20% to 30% of patients with ARF from toxic causes (e.g., ethylene glycol) survived. In addition to providing lifesaving benefits for acute scenarios, dialytic support may be extended to provide additional time for renal repair and recovery. Although the majority of renal recovery has traditionally been thought to occur within 4 weeks of renal injury, I have seen patients with continued recovery over 3 to 6 months.

Renal Transplantation

CHRISTOPHER A. ADIN, *Rochester, New York*

Renal transplantation is widely accepted as the most successful and cost-effective method for the treatment of end-stage renal disease in humans; application of this technique is limited primarily by the availability of suitable organ donors. Pioneering work by Drs. Clare Gregory and Gary Gourley in the late 1980s made clinical application of renal transplantation a reality for dogs and cats with naturally occurring renal disease (Bonagura and Kirk, 1992). However, organ transplantation presents a number of unique surgical, immunosuppressive, ethical, and financial challenges in veterinary patients, slowing widespread application of this technique in veterinary medicine. Fortunately a number of recent advances in each of these areas have improved the success rate and availability of organ transplantation for dogs and cats. These events, coupled with an increasing demand for advanced medical and surgical therapies in veterinary patients with end-stage renal disease, have fueled a strong interest among pet owners seeking the highest level of care for their animals. This chapter summarizes recent advances in veterinary renal transplantation and provides up-to-date information for the veterinary practitioner for identification and referral of appropriate candidates.

PREPARATION FOR RENAL TRANSPLANTATION

Indications for Renal Transplantation

Renal transplantation is offered as one of several methods to manage cats and dogs with moderate-to-severe end-stage renal disease. Evidence from large retrospective studies performed in humans would indicate that early and aggressive management of renal disease with hemodialysis or renal transplantation leads to improved outcome in affected patients. In fact, the 1993 National Institute of Health Consensus Statement on the Morbidity and Mortality of Dialysis recommended that men with a serum creatinine concentration of 2mg/dl should be referred to a nephrologist for predialysis and transplant evaluation. Similarly, early referral is recommended by veterinary transplant centers to allow development of a relationship with the client, to allow time for adequate screening of recipients, and to facilitate a well-informed client decision when the time for intervention arises. Renal transplantation is most successful when performed as an elective procedure in stable cats and dogs with serum creatinine between 3g/dl and 10mg/dl. In animals with more severe degrees of azotemia, preoperative hemodialysis may be required.

Screening of Transplant Candidates

Original screening criteria for veterinary transplant candidates were based on exclusion criteria used in human medicine. A broad array of preoperative tests was recommended; and identification of any serious organ dysfunction, endocrine disease, or infectious process not related to the primary renal disease was considered a contraindication for kidney transplantation. As experience in veterinary renal transplantation accumulates, retrospective analysis has allowed us to revise these screening criteria and in general has led to a less restrictive policy at most institutions (Fig. 195-1). For example, original guidelines suggested that any cat with abnormal findings on echocardiogram should be declined for renal transplantation. However, a recent retrospective analysis indicated that mild, focal changes in ventricular septal wall thickness were present in the majority of cats with chronic renal failure and may represent changes secondary to hypertension or uremia rather than primary cardiac disease (Adin et al., 2000). Minor echocardiographic changes were not predictive of postoperative complications and should not serve as an absolute contraindication to renal transplantation (Adin et al., 2000). Instead more severe changes representative of primary hypertrophic cardiomyopathy (diffuse or severe hypertrophic changes) or evidence of preexisting heart failure is now considered to be of more significance in screening of feline transplant candidates. A variety of other factors such as severe preoperative azotemia or unmanaged hypertension have now been shown to contribute to the occurrence of postoperative neurologic abnormalities (Adin et al., 2001; Kyles et al., 1999). Although these factors are not absolute contraindications to renal transplantation, correction of preoperative azotemia and hypertension through medical therapy or hemodialysis is recommended in cats with more severe stages of renal dysfunction. Other preoperative findings such as severe cachexia or urinary tract infection may be addressed with aggressive medical therapy and reevaluated by the transplant center, as indicated in Fig. 195-1.

Animals with preexisting infectious diseases are at particularly high risk of experiencing complications after immunosuppressive therapy is initiated; renal transplantation may not be the most advisable method of treatment in these animals. For this reason, renal transplantation is not recommended in cats with feline leukemia virus infection or active feline immunodeficiency virus infection. Caution is also advised in cats housed in multicat households that include cats with known infectious diseases. Positive immunoglobulin (Ig)G titers to *Toxoplasma gondii* are not an absolute contraindication to renal transplantation, and veterinarians should consult with the

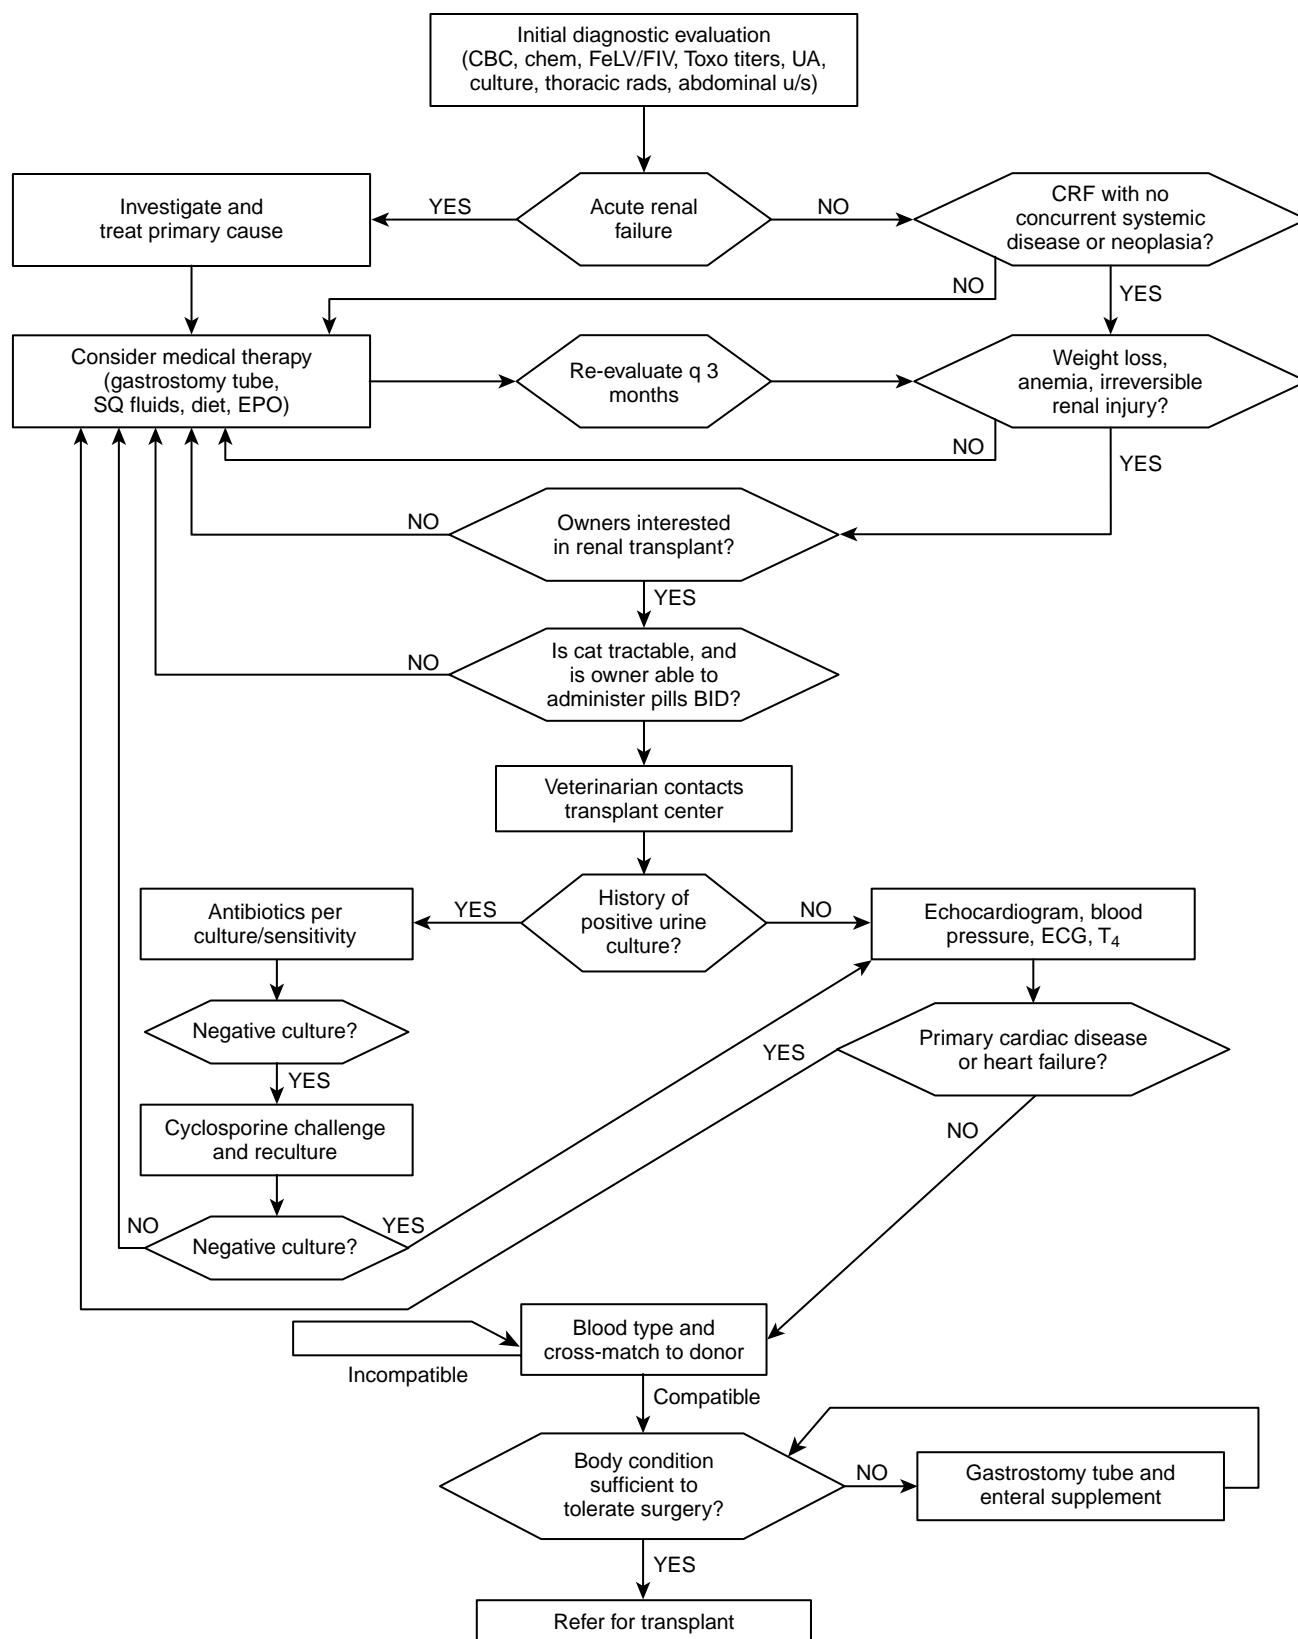

Fig. 195-1 Screening criteria for transplants.

transplant center about specific policies regarding toxoplasmosis and other infectious diseases. Transplant center clinicians are often able to provide assistance in maximizing medical therapy for end-stage renal disease, even if transplantation is not recommended. In some animals with more moderate degrees of azotemia (creatinine less than 6 mg/dl), aggressive therapy with gastrostomy tube placement, fluid therapy, dietary modification, and erythropoietin may provide survival times that parallel those following renal transplantation (see Chapter 190 and other chapters in this section).

Identification and Screening of Renal Transplant Donors

Using modern immunosuppressive protocols, feline kidney transplantation may be performed using unrelated donors with low risk of organ rejection. As a result, feline kidney donors may be obtained from a source of healthy cats that are in need of adoption such as a research colony or animal shelter. Screening of the donor involves standard hematologic analysis, serum biochemistry panel, urinalysis, and infectious disease screening (feline leukemia virus, feline immunodeficiency virus, and IgG/IgM titers for *Toxoplasma*). Imaging of the urinary tract is performed by intravenous pyelography or abdominal ultrasound to confirm the presence of two structurally normal kidneys. Prospective recipients are blood typed and then crossmatched to three or more donors. Tissue typing is not typically performed.

Allograft rejection is more difficult to prevent in dogs than in cats; the best successes are achieved when using related or tissue-matched donors. Aside from screening for general health and blood crossmatching as described previously, additional dog lymphocyte antigen (DLA) typing is recommended before selecting a canine kidney donor. Coordination of DLA typing can be completed by the transplant center before referral of canine transplant candidates.

Use of animal organ donors has stimulated an ethical debate in veterinary medicine that is similar to the one that surrounds live organ donation in humans. In retrospective studies of both veterinary and human transplant donors, the risks of perioperative complications or long-term morbidity associated with kidney donation are extremely small. Currently all veterinary transplant centers require that the owner of the organ recipient, regardless of outcome, adopt the kidney donor and provide lifelong care—a process that has provided excellent homes to over 400 cats in the United States over the last 20 years. Alternative sources of organs are extremely limited in veterinary medicine, and the resources required to form an organ-sharing network modeled on the human transplant system are not available. However, with improvements in cold organ preservation in dogs and cats, cadaveric organ donation may become available in the future.

Availability of Renal Transplantation

A number of veterinary transplant programs have been established across the country since the inception of clinical renal transplantation in the late 1980s, providing

services to clients in each major region of the United States (Box 195-1). Most centers maintain informative websites, with general information about renal transplantation, specific guidelines, and contact information for each institution. For most efficient communication of medical information, it is recommended that the referring veterinarian (not the client) make the initial contact with the referral center.

THE TRANSPLANT PROCEDURE

Surgical Procedure

In principle the current surgical technique for implantation of a renal allograft in the dog and cat is similar to that established by Gregory and Gourley in their original description of clinical renal transplantation (Gregory et al., 1987). Renal allograft transplantation involves implantation of the donor kidney into the caudal abdomen of the recipient. Blood supply to the kidney is established through surgical anastomoses of the donor artery and vein to the recipient vasculature; urine drainage is established by implantation of the ureter into the urinary bladder. With few exceptions the native kidneys are retained to provide a baseline level of renal function and fluid removal during periods of allograft dysfunction (a fact that is often surprising to pet owners). As with any complex procedure, technical experience obtained over the past 20 years has led to discovery of a number of species-specific surgical complications. Subsequently procedures have been modified in an attempt to minimize surgical morbidity and mortality.

Ureteral implantation is perhaps the most technically challenging aspect of renal transplantation in the cat, and the high incidence of ureteral obstruction in the immediate postoperative period is a major cause of delayed graft function. Originally intravesicular techniques were used, progressing from a simple “drop in” technique in which the ureter was pulled through a defect in the bladder wall and tacked to the interior of the bladder with a single transmural suture (Kochin et al., 1993) to direct apposition of the ureteral and bladder mucosal using interrupted sutures (Gregory et al., 1996). Unfortunately intravesicular techniques were associated with a high rate of granuloma formation and ureteral obstruction. More recently experimental studies have demonstrated that extravesicular implantation of the ureter into the bladder may decrease the incidence and severity of postoperative ureteral obstruction, as well as the duration and technical difficulty of the procedure (Mehl et al., 2005). Excision of the entire ureteral papilla from the donor cat also decreases the risk of ureteral obstruction during implantation (Hardie et al., 2005). Improvements in ureteral implantation techniques not only have benefited cats receiving renal transplants but are frequently applied in cats with upper urinary tract obstructions secondary to ureteral calculi or ureteral trauma.

Despite a number of innovations in methods for vascular anastomoses, most transplants are still performed by hand suturing of the vessels using microsurgical techniques. Surprisingly, vascular obstruction or primary failure of vascular anastomoses is not encountered frequently in veterinary transplantation, despite the small size of the patients and the technically demanding nature of vascular surgery. However, other complications have led to important modifications of the originally described surgical techniques over the past decade. For example, transplanted kidneys are quite mobile after implantation into the abdomen; and initial attempts to stabilize the kidney with interrupted sutures placed between the renal capsule and body wall were found to be inadequate, resulting in the tragic occurrence of postoperative renal pedicle torsion in a small number of animals. In both dogs and cats the implanted kidney is now stabilized using a *transversus abdominis* muscle flap, which is raised from the lateral aspect of the abdominal wall and sutured to the renal capsule, cradling the kidney in a sling of muscle. Unilateral hind limb ischemia is a similarly devastating but infrequent complication in feline renal transplant recipients secondary to use of the external iliac artery and common iliac vein as recipient vascular pedicles. Vascular anastomoses are now performed to the caudal abdominal aorta and vena cava in an end-to-side fashion, eliminating problems with hind limb ischemia (Bernsteen et al., 1999). As an added benefit, end-to-side anastomotic techniques circumvent problems associated with differences in size of donor and recipient vessels that cause difficulty when performing end-to-end anastomoses.

A final area of surgical technique modification has been the application of enteroplication in dogs receiving renal allograft transplantation. Interestingly, experimental and clinical experiences have shown that dogs have a high incidence of intussusception following renal allograft implantation. Accordingly, surgeons now recom-

mend enteroplication as part of the transplant procedure (Kyles et al., 2003). Preoperative and intraoperative opioid administration is also believed to decrease the incidence of this complication in dogs and has been incorporated into the standard anesthetic regimen for canine renal transplantation. Postsurgical intussusception appears to be a species-specific problem, and enteroplication is not currently recommended in cats undergoing renal transplantation.

Organ Preservation

Recent experimental evidence and clinical data from human renal transplantation have indicated that early ischemic injury to the transplanted organ leads not only to delayed function of the graft but also causes an antigen-independent stimulation of the immune system and can lead to chronic rejection of the organ. This new recognition of the significance of ischemic injury has bolstered research into methods of graft preservation, even with the brief periods of organ storage that are encountered when using live donors in veterinary transplantation. Several preservation solutions are available for use in humans receiving organ transplants, but the cost and inconvenience of storing and using these solutions has limited their use in veterinary transplant centers. Fortunately a simple and inexpensive preservation solution has been introduced for use in feline renal transplantation, replacing the cold heparinized saline flush that was used for the past two decades in many transplant centers (McAnulty, 1998).

POSTTRANSPLANTATION ISSUES

Immunosuppression

The discovery of cyclosporine, a calcineurin inhibitor with specific anti-T cell activity, was arguably the crucial development that transformed renal transplantation from an interesting idea into the treatment of choice for humans with end-stage renal disease. The simple combination of cyclosporine with a corticosteroid, one of the original immunosuppressive protocols, has proven to provide long-term success in feline renal transplant recipients with few side effects. As a result, this protocol is still used as the primary method of therapy for cats receiving renal allografts. Pharmacokinetics of cyclosporine varies greatly in cats; therapeutic drug monitoring is required at frequent intervals for the remainder of the recipient cat's lifetime. Transplant recipients initially receive cyclosporine at a dosage of 4 to 5 mg/kg every 12 hours; subsequent doses are titrated to maintain 12-hour trough blood levels between 250 and 300 ng/ml. Various formulations of cyclosporine are available, and each form has different bioavailability. The microemulsified form of oral cyclosporine (Neoral, 100 mg/ml, Novartis) is currently recommended. To ensure complete dosing of this liquid and to avoid a negative association with the bad taste of oral cyclosporine, the drug is drawn up in a tuberculin syringe and injected into an empty gelatin capsule (size 000 or 0000). Prednisolone tablets may also be added to the capsule before administration to decrease the number

of tablets or capsules administered. In patients that are resistant to oral medication, long-term maintenance of a low-profile gastrostomy tube can allow direct administration of liquid cyclosporine followed by 5 to 10 ml of water flush. High-profile lipid chromatography analysis continues to be the most accurate cyclosporine assay; clients must mail blood samples to specific centers that offer this method of analysis. Drug level monitoring is performed weekly in the initial postoperative period and is then continued at a minimum interval of 2 to 3 months in stable patients. At this time immunosuppressive drugs are continued for the life of the animal.

Recent studies in the area of transplant immunosuppression have not only led to novel agents for immunosuppression but have described novel combinations of existing immunosuppressive drugs. One important contribution has been the discovery that ketoconazole, an antifungal agent, may be used at subtherapeutic doses to decrease the amount of cyclosporine required in both dogs and cats (Dahlinger, Gregory, and Bea, 1998; McNulty and Lensmeyer, 1999). Ketoconazole acts by inhibiting hepatic cytochrome P-450 enzymes involved in metabolism of cyclosporine and when given concurrently with cyclosporine the dose of cyclosporine can be reduced. When ketoconazole was given to dogs (5 to 14 mg/kg once a day), the total dose of cyclosporine could be decreased by 38% to 75%. Cats given ketoconazole (10 mg/kg/day) administration allowed conversion to a once-a-day regimen for cyclosporine (usually 4-5 mg/kg). The benefits of ketoconazole administration are numerous, with potential for increased compliance (once-a-day dosing of cyclosporine is possible), up to 58% decrease in cost of medications, decreased incidence of opportunistic fungal infections, and potential for decreased rejection rate in patients receiving combination therapy. Because of cytochrome P-450 inhibition, ketoconazole may cause hypoalbuminemia, weight loss, and hepatotoxicity in some animals; periodic monitoring of liver enzymes is indicated in patients receiving chronic combined cyclosporine and ketoconazole therapy.

In contrast to the situation in cats, it has proven extremely difficult to achieve a balanced, affordable immunosuppressive protocol that consistently results in long-term survival following renal transplantation in unrelated dogs. However, recent successes in both clinical and experimental canine transplantation would suggest that improvements might be on the horizon for dogs with end-stage renal disease. A group at the University of California, Davis, have reported their clinical experience in 15 dogs using three well-known immunosuppressive drugs (prednisolone, azathioprine, and cyclosporine) in a novel combined protocol (Gregory et al., 2006). Allograft rejection was prevented with this three-drug protocol, but the frequent occurrence of opportunistic infections in many recipients suggested an excessive level of immunosuppression. Perioperative thromboembolic events also led to several deaths early in the study, although addition of enoxaparin (a low-molecular weight heparin compound) prevented this complication in the last six dogs treated. Meanwhile, an experimental study performed at the University of Wisconsin, Madison, evaluated the efficacy of an exciting new pyrimidine antimetabolite

capecitabine (Xeloda, F. Hoffman, La Roche Ltd.), in dog lymphocyte antigen (DLA)-matched beagles (Schmiedt et al., 2006). Capecitabine used in combination with prednisolone and cyclosporine was highly effective in preventing allograft rejection. Another group at Auburn University has begun an aggressive attempt to induce immunologic tolerance (long-term allograft function without a requirement for immunosuppressive drugs) in the dog (Broadus et al., 2006). In this protocol dogs are exposed to myeloablative (whole body) irradiation followed by concurrent donor bone marrow and renal allograft transplantation. Dogs were administered cyclosporine and mycophenolate-mofetil for 60 days after surgery; immunosuppressive drugs were then tapered and discontinued. DLA-mismatched dogs had long-term survival and allograft function even after drug withdrawal, although there was histologic evidence of allograft rejection in all samples at 228 to 580 days. Although success in canine renal transplantation continues to lag behind that achieved in cats, a number of novel approaches to manipulate the immune response to allograft tissues may provide a solution to this difficult problem in the near future.

Cost

The cost of renal transplantation varies at each institution, ranging from \$5000 to \$8000 for cats and from \$7,000 to \$12,000 for dogs. Extended postoperative care can double the overall cost in some animals that experience postoperative complications. In addition, clients should be warned of the recurring cost of lifelong immunosuppressive drugs and laboratory testing, with costs ranging from \$100 to \$200/month in cats and from \$400 to \$600/month or more in dogs.

Outcome

Reliable statistics on outcome of veterinary transplantation in cats are now becoming available as transplant centers report the results of renal transplantation in large numbers of animals. Published data suggest that approximately 80% of cats survive the perioperative period and are discharged from the hospital and approximately 60% survive the first 6 months after kidney transplantation (Adin et al., 2001). Interestingly, the majority of cats that survive the first 6 months go on to enjoy long-term survival, with 42% of cats remaining alive 3 years after surgery. Overall median survival in the largest reported case series was 22 months (Matthews and Gregory, 1997). At the time of renal transplantation, mean serum creatinine values were approximately 8 mg/dl, and medical options typically had been exhausted. These figures reflect an important message for clients of prospective transplant recipients—renal transplantation has the potential to markedly increase the quality and duration of life in cats with advanced renal failure, but recipients are not expected to have life spans comparable to that of a normal cat.

Prognosis for dogs after renal transplantation is much more difficult to gauge because of the small number of canine transplants that are performed and the variation

in immunosuppressive regimens that are used at different institutions. In addition, survival of dogs in experimental studies of renal transplantation often exceeds that of dogs with naturally occurring renal disease that are treated with the same protocol. Current clinical reports suggest that only about 50% of dogs survive the first 2 months after kidney transplantation and that a high rate of opportunistic infections may occur in patients that survive long term (Gregory et al., 2006). As clinical experience increases and novel immunosuppressive protocols are developed, it is expected that survival and quality of life will improve for dogs much as it did for cats receiving renal transplants over the last 20 years.

CHAPTER 196

Gastrostomy Tube Feeding in Kidney Disease

DENISE A. ELLIOTT, *St. Charles, Missouri*

Dietary therapy has remained the cornerstone of management of chronic kidney disease for decades. The goals of dietary modification are to meet the patient's nutrient and energy requirements; alleviate clinical signs and consequences of the uremic intoxication; minimize disturbances in fluid, electrolyte, vitamin, mineral, and acid-base balance; and slow progression of the renal failure. Recent clinical studies have clearly demonstrated the beneficial effects of dietary therapy in reducing uremic symptoms and slowing disease progression (Elliott et al., 2000; Jacob et al., 2002) (see Chapter 190). However, for the nutritional modifications to be effective at ameliorating

the clinical signs of uremia, the pet must be prescribed and consume the appropriate diet. This task can clearly be challenging in the patient with renal disease.

Patients with chronic kidney disease are often anorectic and have reduced appetites. Adequate daily dietary intake is further hampered by uremic manifestations such as nausea, vomiting, and gastric ulcerations. In addition, an altered sense of taste and smell, reported in uremic people, may also affect dogs and cats. These factors combine to reduce caloric intake and refusal of the diet, a common problem reported by many owners. The subsequent protein-calorie malnutrition and wasting contribute to many

aspects of uremia, including impaired immune function, increased susceptibility to infection, delayed wound healing, decreased strength and vigor, and increased morbidity and mortality. Indeed, protein-calorie malnutrition has been implicated as a key factor influencing outcome in humans with renal failure. Therefore prevention of malnutrition by ensuring adequate nutrient intake is considered crucial in the management of renal failure.

NUTRITIONAL ASSESSMENT IN CHRONIC KIDNEY DISEASE

Optimal initiation of nutritional support requires early assessment of patients to identify those either at risk of malnutrition or that already require nutritional support. Nutritional assessment includes evaluation of the history, physical examination, body weight (BW), body condition score (BCS), and laboratory data. The type, amount, and frequency of food intake and the incidence of vomiting should be noted. A food diary can be used to record daily intake. The daily caloric intake should be compared with the calculated daily caloric requirements. Manifestations of inadequate nutrient intake include loss of BW or BCS, hypoalbuminemia, and anemia. However, alterations of common laboratory indicators of malnutrition (albumin, blood urea nitrogen, cholesterol, erythrocyte mass, and lymphocyte counts) are often indistinguishable from those that can occur with chronic kidney disease and other concurrent disease processes. Other markers of nutritional status, including prealbumin, transferrin, and ceruloplasmin, have not been fully evaluated in feline and canine patients. Objective determination of alterations in fat mass or lean body mass using total body water, dual energy x-ray absorptiometry, and bioelectrical impedance analysis are more precise measures of body condition but are not widely available.

RATIONALE FOR GASTROSTOMY TUBE FEEDING

Practical measures to improve food intake include the use of highly odorous foods, warming food before feeding, and stimulating eating by positive reinforcement (such as petting and stroking behavior). Appetite stimulants such as benzodiazepines or serotonin antagonists may be administered judiciously; however, these methods are often ineffective in the uremic patient. Effective dietary management for patients in which daily caloric intake cannot be sustained with oral feeding can be accomplished with the aid of a gastrostomy tube. Gastrostomy tubes are ideal for long-term enteral access because they are associated with fewer upper airway complications and have a larger diameter than nasogastric and most esophagostomy tubes. Esophagostomy tubes are useful for short-term (days to weeks) dietary management in animals expected to recover from a transient insult or crisis (also see Chapter 136).

Gastrostomy tubes should be instituted for nutritional support on documentation of a 10% to 15% loss of BW in conjunction with a declining BCS and a history of poor dietary intake. Enteral feeding such as with a gastrostomy tube is indicated for patients with an intact, functional

gastrointestinal system. Gastrostomy tubes are advantageous not only for supplying nutrients but also for easing the administration of fluid and medications, all of which can be delivered via the tube.

At first some owners are concerned not only about the appearance of the gastrostomy tube on their pet but about the time commitment and technical ability required for at home care of gastrostomy tubes. Therefore part of patient selection process necessitates detailed discussions and reassurance that the client can provide the appropriate resources to optimize the care of the patient.

GASTROSTOMY TUBE PLACEMENT

Equipment Requirements

Gastrostomy tubes are available in several sizes; 18 to 20 Fr are appropriate for cats or small dogs, and 24 Fr are adequate for larger dogs. Gastrostomy tubes generally are composed of latex or silicone. The selection of tube composition depends on the expected duration of use, biocompatibility, and cost. Latex tubes are less expensive but generally require replacement within 8 to 12 weeks because of tube wear and tear. Silicone tubes are softer and flexible and have a long life; however, they are generally more expensive than the other tubes. Silicone tubes typically survive 6 to 12 months and appear to be less irritating at the stoma site.

Various designs are available. The most common choice for initial placement is a latex Pezzet catheter (with a mushroom tip). Cost-effective preassembled kits are available commercially. Replacement tubes typically are Foley catheters (with a balloon at the tip). An array of feeding adapters can be attached to the gastrostomy tube; I prefer a Y-port device that has both catheter and Luer tip syringe ports (Bard Dual Port Feeding Adapter, Bard Access Systems, Inc.). Blended food can be delivered easily using the catheter port, and oral medications can be administered via the Luer port.

Low-profile gastrostomy tube devices (LPGDs) have been developed for use as both initial and replacement tubes. These devices are positioned flush with the body wall. Client and patient acceptance is much higher than with traditional tubes because the patient still appears "normal," without a long tube attached to the body or an obtrusive stockinette cover. Indeed, in one study LPGDs were the preferred replacement devices in 62% of dogs (Elliott, Riel, and Rogers, 2000). LPGDs are constructed of silicone, which improves tissue biocompatibility and appears to cause less stoma site inflammation. In addition, the mushroom tip has an antireflux valve design to prevent reflux of gastric contents. A feeding adapter is attached to the end of the device during the feeding procedure. LPGDs are expensive but have been documented to last at least 12 months. Thus the additional cost of the LPGD may be offset by the decreased frequency of replacement.

Tube Placement Procedure

Gastrostomy tubes can be placed using a surgical or percutaneous approach. Percutaneous placement is preferred

since it requires a shorter period and lighter plane of anesthesia compared to surgical placement. There are two percutaneous techniques, one using an endoscope (percutaneous endoscopic gastrostomy (PEG) tubes) and one performed as a blind technique.

Gastrostomy tube placement is a 10- to 20-minute procedure requiring general anesthesia. Selection of anesthetic agent depends on the patient; however, special considerations are relevant in renal failure patients. Agents should be selected for their minimal effect on the cardiovascular and renal systems, lack of nephrotoxicity, and minimal requirement for renal excretion. A preanesthetic antimuscarinic (atropine) and sedative (oxymorphone or butorphanol), followed by an intravenous anesthetic induction agent (propofol-diazepam combination) and inhalation anesthesia (isoflurane) are appropriate choices. Intraanesthetic preservation of renal function may be supported by maintaining adequate intravascular volume with crystalloid fluids (e.g., lactated Ringer's solution) and supporting intravascular pressure. Low-dose dopamine (dogs) or mannitol (dogs and cats) infusion may be required to increase renal blood flow, glomerular filtration rate, and diuresis in individual cases.

The patient is placed in right lateral recumbency to allow the gastrostomy tube to be positioned on the left side along the greater curvature of the stomach. An area on the left of the patient, 1 to 2 cm caudal to the last rib and midway between the dorsal and ventral midline, is clipped and prepared with an antiseptic regimen. A mouth gag is placed to protect the endoscope from accidental damage. The endoscope is passed into the stomach, and the stomach is insufflated with air until it is distended. Gastric distention facilitates the positioning of the gastrostomy tube by pushing the stomach against the abdominal wall, displacing the spleen caudally and ventrally and moving the colon caudally. Monitoring oxygen saturation with a pulse oximeter or mechanical ventilatory assistance is important because gastric distention can cause ventilatory and circulatory compromise. An assistant wearing sterile gloves gently probes the area behind the last rib (about one third of the distance from the epaxial musculature to the ventral midline) with a finger while the endoscopist selects the appropriate location on the greater curvature of the stomach. Transillumination and palpation should ensure that the spleen is not present between the stomach and the abdominal wall. An 18-gauge, 1½-inch needle is inserted transabdominally into the gastric lumen. Sterile nylon suture (0-0) is passed through the hub of the needle and advanced into the gastric lumen. The suture is grasped using endoscopic retrieval forceps, and the endoscope and forceps with attached suture are slowly withdrawn out the mouth. A pair of hemostats placed on the other end of the suture material ensures that the abdominal end of the suture is not inadvertently pulled through the abdominal wall. The oral end of the suture is secured to the catheter tip of the gastrostomy tube, and the gastrostomy tube is lubricated to facilitate passage through the oral pharyngeal region. The needle is then removed from the abdominal wall, and the assistant pulls the suture with attached gastrostomy tube through the mouth and into the stomach using gentle traction. A small skin incision is necessary to aid the passage of

the gastrostomy tube through the abdominal wall. The endoscope is replaced into the stomach, and the gastrostomy tube site is examined. The mushroom tip should sit comfortably on the gastric wall without "blanching" the gastric mucosa; however, close apposition of the gastric and abdominal walls should be maintained. If the tube is pulled too tight, it may cause pressure necrosis of the gastric wall with subsequent complications (intraperitoneal leakage of gastric contents, tube migration). The stomach should be deflated, and the position of the tube rechecked before exit of the endoscope. The position of the tube on the exterior abdominal wall is marked with a permanent marker to facilitate identification of tube migration. A phalange is placed on the exterior portion of the tube to aid immobilization, and the tube is sutured to the external body wall using butterfly wings. The external clamps and feed adaptor devices are attached to the tube. Antibiotic ointment is applied to the stoma site, and a stockinette and Elizabethan collar are placed on the patient to prevent tube dislodgement.

Dietary Selection and Gastrostomy Tube Management

Water is introduced through the tube 12 to 18 hours following initial placement, and feeding is scheduled to begin within 24 to 36 hours. Several commercial diets specifically formulated for the management of the renal patient are available. Human enteral products are inappropriate because of expense and nutritional inadequacy for dogs and cats (e.g., insufficient protein, taurine, arachidonic acid, arginine). On selection of the diet the daily energy and requirements should be calculated. Dogs should be fed $132 \times \text{BW}(\text{kg})^{0.75}$, and cats require 60 kcal/kg/day. Caloric requirements can vary by 25%; thus actual caloric intake needs to be individualized based on serial BW and BCS. An estimation of daily caloric intake can be determined by reviewing the caloric intake that sustained ideal BW when the pet was healthy. The diet is blended with the least amount of water required to achieve syringability. The total volume of food is divided into four to six equal-sized meals, which should not exceed the gastric capacity of the patient (45 to 90 ml/kg). Generally one fourth to one third of the daily caloric intake is administered on the first day. If no complications occur, the amount fed is successively increased to reach total caloric requirements by the third or fourth day. With time and adaptation to the feeding procedure, the meal frequency may be reduced to a convenient BID-to-TID daily schedule. The patient's appetite may wax and wane; thus a meal can be offered orally and, if not consumed, can be blended and administered via the tube.

Before every meal, the gastric contents should be aspirated with a syringe. If more than 50% of the prior feeding is present, the contents should be returned to the stomach, and the feeding skipped until the next scheduled time. Frequent aspiration of the previous meal may suggest delayed gastric emptying and warrant medical management (e.g., metoclopramide 20 to 30 minutes before feeding).

Oral medications should be administered before feeding, with the exception of phosphate binders, which

must be mixed directly with the food. The food should be warmed to room temperature and administered slowly over 5 to 15 minutes. Salivation and patient discomfort suggest nausea, which may be handled by slowing the rate of feeding. On completion the tube should be flushed with 5 to 10 ml of water.

The position of the tube on the body wall should be examined daily for migration; and the stoma site inspected for pain, redness, odor, and discharge. The site should be cleaned daily with an antiseptic solution, and antimicrobial ointment applied. Food residue should not be left near the stoma.

COMPLICATIONS OF GASTROSTOMY TUBE FEEDING

Complications of Tube Placement

Splenic laceration, gastric hemorrhage, pneumoperitoneum, displacement into the peritoneal cavity, and peritonitis have been reported as infrequent gastrostomy tube placement complications. The risk of splenic laceration can be reduced by adequate insufflation of the stomach and palpation to ensure that the spleen is not located between the stomach and the body wall. Postplacement intragastric bleeding, likely a complication of severe uremia and gastroenteritis, was the most frequent complication noted in one study of dogs with chronic kidney disease (Elliott, Riel, and Rogers, 2000). However, the bleeding did not cause any apparent clinical morbidity. Gastrostomy tube displacement into the abdominal cavity may be recognized by the development of fever and abdominal pain. Tube displacement is more likely if (1) the gastrostomy tube is secured too tightly, leading to pressure necrosis of the abdominal wall; (2) an internal flange is absent; (3) and the external flange is adjusted inappropriately.

Stoma Site Complications

Abnormalities at the stoma site may include discharge, pain, tissue swelling, erythema, abscess formation, and ulceration. Stoma site complications have been reported in 46% of dogs with chronic kidney disease (Elliott, Riel, and Rogers, 2000). This seemingly high incidence may be a consequence of impaired immune function, increased susceptibility to infection, and delayed wound healing associated with malnutrition and/or uremia. The high incidence of peristomal complications highlights the necessity of meticulous stoma site care. Abnormalities at the stoma site can be minimized by strict attention to cleaning of the stoma site with an antiseptic solution and application of an antibiotic ointment around the stoma site. In addition, the patient should be prohibited from licking the site through the permanent placement of a stockinette. Warm packs containing antiseptic solution placed on the stoma site may minimize problems or hasten recovery.

Patient Removal of the Tube

Inappropriate patient removal of the tube is undoubtedly the most problematic complication. In one study approximately 20% of dogs removed their gastrostomy tubes,

which emphasizes the importance of restraining the gastrostomy tube in a stockinette and using Elizabethan collars (Elliott et al., 2000). Patient removal of the gastrostomy tube is considered an emergency situation and indeed may lead to life-threatening intraperitoneal leakage of gastric contents if the stomach has not yet adhered to the body wall. In most situations a new tube can be placed through the existing stoma site using a guide catheter. On the other hand, if the tube has been in place for less than 7 days or there is evidence of peritonitis or radiographic contrast agent leakage, an exploratory laparotomy is required to correct the situation. Because of their short length and inaccessibility, the use of LPGDs may reduce the incidence of inadvertent gastrostomy tube removal.

Complications during the feeding process, including salivation, gulping, retching, and vomiting, can be minimized by reducing either the total volume at each feeding (increasing the frequency of feeding to maintain caloric intake) or the rate of administration. Simultaneous management of fluid, electrolyte, and acid-base disturbances contributing to uremic gastritis may reduce the incidence of vomiting.

Periodically gastroscopy tubes become blocked with food. Techniques to facilitate removal of the obstruction include massaging the outside of the tube while simultaneously flushing and aspirating with water; instilling carbonated drinks, meat tenderizers, or pancreatic enzyme solutions (allow to soak within tube for 15 to 20 minutes); or gently using a polyurethane catheter to dislodge the obstruction. The final resort for a blocked tube is tube removal and replacement.

REPLACEMENT OF GASTROSTOMY TUBES

Reasons to replace the initial gastrostomy tube include inappropriate patient removal, the convenience of the LPGD, tube malfunction, blockage, or tube wear and tear. If the original gastrostomy tube has been in place for more than 7 to 10 days, adhesion of the stomach to the body wall should have occurred. In this situation the original gastrostomy tube can be removed by placing firm traction on the outside of the tube. The method of replacement depends on the type of replacement tube. For LPGD devices an obturator is inserted down the center of the LPGD and used to stretch the end of the device to form a transient linear structure, which then is inserted into the stoma. Once placed in the stomach, the obturator is removed.

For replacement with a traditional balloon-type gastrostomy tube, a polyurethane catheter is inserted through the stoma. The polyurethane catheter is used as a guide, and the replacement gastrostomy tube is threaded over this guide into the stomach. Once in place, the balloon is insufflated, and the polyurethane catheter removed. Regardless of the replacement technique used, appropriate replacement of the tube within the gastric lumen should be verified radiographically using survey radiographs or after iodinated contrast media is injected through the new tube.

Exploratory laparotomy is necessary for replacement if the gastrostomy tube has been removed before gastric-abdominal adhesion formation, if the tube tip is displaced

into the abdominal cavity, or if the sealed stoma is perforated inadvertently during percutaneous replacement.

MONITORING AND OUTCOME

Gastrostomy tubes have been used to provide nutritional support in dogs with chronic kidney disease for as long as 438 days. Elliott, Riel, and Rogers (2000) reported that BW increased in 22% of dogs with chronic kidney disease following gastrostomy tube placement. Declining BW was stabilized in a further 31% of dogs. However, 30% of dogs continued to lose BW despite gastrostomy tube placement. These results highlight the necessity for repeated nutritional assessment and aggressive alterations in dietary intake to ensure stabilization or gain of BW rather than continued loss of BW. In addition to low caloric intake, BW changes in uremic patients may be influenced by metabolic acidosis and chronic inflammation; both stimulate protein catabolism and loss of lean body mass. Thus every effort must be made to control metabolic acidosis and aggressively manage coexisting catabolic illnesses.

CHAPTER 197

Systemic Hypertension in Renal Disease

MARK J. ACIERNO, *Baton Rouge, Louisiana*

Hypertension is a common sequela to kidney disease and is thought to affect as many as 19.4% of feline and 61% of canine renal failure patients. Normal blood pressure is the result of complex interactions among the heart, kidney, endothelial signaling mechanisms, and the autonomic nervous system (Fig. 197-1). These factors establish systemic vascular resistance and cardiac output, which are the final determinants of blood pressure. Although the association between renal failure and hypertension has been studied extensively in humans and in animal models, the exact cause of the blood pressure elevation is not known.

DEFINITION AND SIGNIFICANCE OF HYPERTENSION

In recent years clinicians and investigators have achieved a better understanding of blood pressure measurements expected in healthy dogs and cats. As a result, the definition of hypertension has been refined. It is now believed that blood pressure measurements greater than 150/95 mm Hg on three separate visits in a patient that demonstrates no clinical signs directly attributable to the blood pressure elevation is compatible with systemic hypertension, as is a single reading of greater than 150/95 mm Hg in a symptomatic patient (see also Chapter 159).

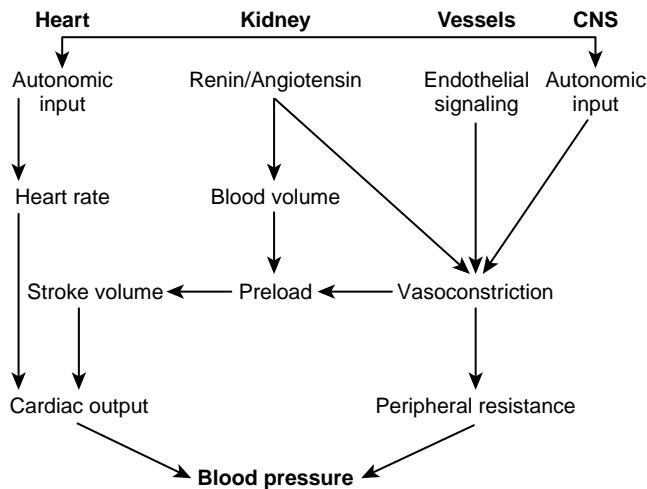

Fig. 197-1 The complex relationship between the heart, kidneys, endothelial signaling, and autonomic nervous system and how they establish blood pressure.

Although patients with mild increases in blood pressure fail to demonstrate clinical signs directly attributable to their hypertension, more dramatic pressure increases can lead to significant renal, ocular, cardiac, or central nervous system injuries. Renal disease is a recognized cause of hypertension, however, persistent blood pressure elevations from any cause can contribute to glomerular and tubular damage. Hypertensive retinopathy and choroidopathy, manifested as retinal edema, tortuous vessels, hemorrhage, and retinal detachment, are common manifestations of hypertension. Cats with chronic kidney disease are often brought to the veterinarian for blindness rather than clinical signs directly attributable to kidney disease. In some cases hypertension may precede overt azotemia in cats with early chronic kidney disease. A cardiac murmur, arrhythmia, and gallop rhythm can develop as increased systemic blood pressure leads to cardiac muscle hypertrophy. Hypertensive encephalopathy manifested as head tilt, ataxia, depression, or seizures may develop as blood pressure overwhelms the cerebral vasculature autoregulatory mechanisms.

PRESSURE MEASUREMENT TECHNIQUES

Hypertension secondary to renal disease is common and is associated with significant morbidity and mortality; therefore blood pressure should be measured periodically in affected animals. Direct measurement of patient blood pressure requires the catheterization of a suitable artery and the determination of systolic and diastolic pressure by an electronic transducer. Although this is considered to be the gold standard of blood pressure measurement, it is neither convenient nor practical in the clinical setting. Rather veterinarians rely on Doppler and oscillometric techniques as noninvasive, indirect measures of patient blood pressure.

Because of its low cost, ease of use, and suitability for use in all companion animals, the Doppler flow detector is a common method for measuring blood pressure.

The only equipment needed other than the detector is a sphygmomanometer and a selection of cuffs in different sizes. Doppler flow detectors work by emitting ultrasound waves and then “listening” for the waves to be reflected back. If there is movement such as blood cells racing through an artery, the frequency of the returned wave is shifted (the Doppler effect). This change in frequency is amplified by the detector and heard by the user as a characteristic “swoosh” sound.

When using the Doppler flow detector, blood pressure is measured by snugly placing a cuff on the proximal portion of any extremity. Ultrasound gel is placed on the Doppler probe, and the probe is then gently placed over any artery distal to the cuff. To improve conduction, the hair over the artery is usually clipped. The cuff is then inflated 20 to 30 mm Hg past the pressure at which blood flow can no longer be heard. Then the cuff is gradually deflated while the operator observes the pressure displayed by the sphygmomanometer. The point at which blood flow can be first heard is the systolic pressure. Often a second sound, which represents the diastolic pressure, can be heard as deflation of the cuff continues. The Doppler flow detector has been validated for use on all cats and dogs, although the limits of agreement between direct and indirect measurements may be somewhat wide. Systolic blood pressure measurement is easily obtained, but determining diastolic pressure is technically challenging.

Oscillometric units are also quite popular because they are automated and can determine systolic pressure, diastolic pressure, mean arterial pressure, and heart rate. These devices work by inflating a cuff around an extremity until arterial blood flow is stopped and then, while slowly decreasing the pressure of the cuff, they monitor for the return of arterial pulsations and arterial vibrations. Despite their convenience, these units can underestimate blood pressure significantly when used on cats and small dogs and is not recommended in these patients.

Regardless of which pressure-measuring technique is used, there are four principles that help to ensure accurate blood pressure measurement: proper cuff size, consistency of personnel and technique, reproducibility of results, and acclimation of the patient. Perhaps the most important factor in attaining accurate blood pressure measurement is the selection of a proper cuff. The width of the cuff should be 30% to 40% of the circumference of the extremity. A cuff that is too wide underestimates blood pressure, whereas an undersized cuff leads to artificially elevated values. A tape measure can be helpful in measuring the circumference of the limb and selecting an appropriate cuff width.

Consistency of technique and personnel is essential to ensure accurate blood pressure measurement. Whenever possible, the same team should be involved in the blood pressure measurement process, and they should use the same technique each time blood pressure is measured. This allows for mastery of blood pressure-taking techniques and development of a consistent methodology.

Blood pressure measurements should be repeated at least three and preferably five times. If there is significant variation between measurements (10%), the entire series should be disregarded and repeated until reproducible results are obtained. A diagnosis of hypertension in

an asymptomatic patient should be confirmed by repeating the blood pressure measurements on two additional office visits.

The stress created by a visit to a veterinary office, known as the *white coat effect*, can cause a profound increase in patient blood pressure. To minimize its impact, blood pressure should always be measured in a quiet area away from other animals and before other procedures are performed. The patient should be allowed to acclimate to its surroundings, and whenever possible the owner should be present. Restraint should be kept to a minimum. Blood pressure measurement should not be attempted in obviously agitated animals.

TREATMENT OF HYPERTENSION

Angiotensin-converting enzyme (ACE) inhibitors are generally considered to be the initial drug of choice in treating canine hypertension (Table 197-1). ACE inhibitors exert their effect by blocking the conversion of angiotensin I to angiotensin II and can lower blood pressure in three ways. First, angiotensin II is a powerful vasoconstrictor; systemic vasodilation occurs when its synthesis is inhibited. Second, angiotensin II directly promotes sodium absorption in the proximal tubule of the kidney leading to intravascular volume expansion. Last, angiotensin II stimulates the release of aldosterone, which also promotes renal sodium and water resorption. Renal insufficiency patients should have their serum chemistry values checked after starting treatment since ACE inhibitors may have the potential to worsen azotemia. As with all antihypertensive medication, ACE inhibitors should be started at the lowest possible dose and increased as needed.

Enalapril is eliminated entirely through renal excretion, whereas both the renal and hepatic mechanisms are involved in the clearance of benazepril. The half-life of enalapril is prolonged in renal failure patients, but the clearance of benazepril appears to be unchanged. This may be because of up-regulated hepatic excretion of benazepril into the bile when renal clearance is compromised. For this reason benazepril may be preferable to enalapril in the treatment of hypertension in renal failure patients. In my experience benazepril is also less likely to cause gastrointestinal upset; however, there are no well controlled studies in clinical patients comparing efficacy or adverse

effects in dogs or cats with spontaneous hypertension. Furthermore, in dogs with severe hypertension and critical target organ injury to the retina or brain, monotherapy with an ACE inhibitor is unlikely to reduce blood pressure sufficiently. In those patients, other treatments are generally required (see below).

ACE inhibitors are less effective in treating hypertension in cats. Studies have shown that as many as 50% of hypertensive cats fail to respond to enalapril. Another study using benazepril demonstrated that, although cats did have a statistically significant decrease in blood pressure, the actual response may be too small to make benazepril useful as a monotherapy agent (Brown, 2001). Therefore dihydropyridine calcium channel blockers are generally considered to be the drug of choice in controlling feline hypertension. Calcium channel blockers exert their effects by blocking the influx of calcium needed to cause smooth muscle contraction and thereby act to decrease systemic vascular resistance. Amlodipine besylate (see Table 197-1) is perhaps the most widely used drug for controlling hypertension in cats. Amlodipine is long acting, gradual in effect, and allows for once-a-day dosing. In humans and dogs calcium channel blocker administration can worsen renal disease despite a significant blood pressure decrease. One possible explanation for this paradoxical effect is that calcium channel blockers preferentially dilate the afferent arteriole of the glomerulus, resulting in glomerular hypertension. Therefore these drugs should not be used as a monotherapy antihypertensive agent in dogs with renal disease. For reasons that are not clear, calcium channel blockers do not appear to have the same effect in cats. Studies have shown that feline patients treated with amlodipine live longer and have fewer hypertensive complications. Therefore calcium channel blockers are considered safe for monotherapy use in cats.

β -Blockers are useful adjunctive therapy in dogs or cats when the initial antihypertensive agent has failed to achieve the desired pressure reduction. β -Adrenergic receptors are found in both the heart (β -1) and lungs (β -2). Blockade of the β -1 receptors slows the heart and lowers blood pressure, but blockade of the β -2 receptors can trigger bronchial constriction and respiratory distress. Therefore a β -1 selective antagonist such as atenolol (see Table 197-1) is preferred for the management of

Table 197-1

Commonly Used Antihypertensive Medications and their Dosages

Drug	Class	Canine Dose	Feline Dose
Enalapril (Enacard, Merck)	ACE inhibitor	0.5-1 mg/kg q12-24h PO	0.25-0.5 mg/kg q12-24h PO
Benazepril (Lotensin, Novartis)	ACE inhibitor	0.25-0.5 mg/kg q12-24h PO	0.25-0.5 mg/kg q12-24h PO
Amlodipine (Norvasc, Pfizer)	Ca ⁺⁺ channel blocker	0.05-0.2 mg/kg q24h PO*	0.625-1.25 mg/cat q24h PO
Atenolol (Tenormin, AstraZeneca)	β -Blocker	0.25-1 mg/kg q12-24h PO	6.25-12.5 mg/cat q12-24h PO
Metoprolol (Lopressor, Novartis)	β -Blocker	0.5-1.0 mg/kg q 8-12h PO	2-15 mg/cat q8h PO
Prazosin (Minipress, Pfizer)	α -Blocker	0.5-2 mg/dog q12h	Not recommended
Spironolactone (Aldactone, Searle Pharmaceuticals)	Aldosterone inhibitors	1-2 mg/kg q12h, PO	1 mg/kg q12h PO

*Higher dosages up to 0.4 to 0.5 mg/kg have been required in refractory patients

hypertension. Atenolol is water soluble and is eliminated by the kidney. The impact of this elimination in patients with azotemia has not been assessed clinically. Atenolol also can be used as cotherapy with amlodipine in the treatment of hypertension associated with hyperthyroidism. However, monotherapy with atenolol is generally ineffective in management of significant hypertension in these cats.

α -Blockers selectively antagonize vascular α -receptors, resulting in vasodilation and decreased blood pressure. Prazosin, a potent α -adrenergic inhibitor, has been used successfully as a primary and adjunctive treatment for hypertension in the dog. Its effectiveness as an antihypertensive agent in cats has not been investigated fully; therefore its use is not recommended except in the most refractory cases.

Recent studies have shown that drugs that antagonize aldosterone may protect the heart, brain, and kidneys from the deleterious effects of hypertension. Although inhibition of aldosterone results in small decreases in blood pressure, the real benefit may be a decrease in hypertension-induced fibrosis of target organs. Therefore hypertensive patients may benefit from the use of spironolactone as an adjunctive treatment (see Table 197-1). Since spironolactone decreases sodium resorption and potassium excretion, it is possible that electrolyte abnormalities could occur when using this drug. Although these abnormalities are unlikely at the dosage recommended, special attention should be paid to electrolytes when rechecking serum chemistries. Additionally, some cats develop skin lesions while receiving spironolactone, and clients should be so warned.

THERAPEUTIC GOALS AND MONITORING

The goal of treating hypertensive patients is to gradually lower systolic pressure to less than 170 mm Hg; blood pressure may not completely normalize. In the initial stages of treatment it is important to monitor the patient regu-

larly and avoid making rapid adjustments in medication. Therapeutic changes can be made at 1- to 2-week intervals unless the patient's condition deteriorates and more immediate modifications are needed. When increasing the dose of the primary antihypertensive medication fails to produce the desired decrease in blood pressure, a secondary antihypertensive in a different drug class should be started. Once systolic pressure has stabilized at acceptable measurements, the patient should be rechecked every 3 months, with complete blood count and serum chemistry results reevaluated at least twice a year (see Chapter 192).

Treatment of Anemia in Renal Failure

MARIE E. KERL, *Columbia, Missouri*

CATHERINE E. LANGSTON, *New York, New York*

Renal failure is a common disease presentation for both dogs and cats. Although patients with either acute renal failure or chronic kidney disease can become anemic, anemia occurs more commonly in patients with chronic kidney disease. Moderate-to-severe anemia is a serious complication of chronic kidney disease. Formulating the differential diagnosis for anemia and accurately identifying the cause or causes provides the clinician with the best means to administer appropriate and timely treatment. This article reviews the common causes of anemia associated with renal failure, suggests diagnostic plans, and outlines currently available treatment options.

ETIOLOGY OF ANEMIA

The basic mechanisms of anemia include blood loss, red blood cell (RBC) destructive processes, and failure of bone marrow production. In some animals with renal failure, more than one etiology contributes to anemia. All possible mechanisms should be considered in each anemic patient regardless of renal disease status to avoid “tunnel vision.” The basis for anemia of renal failure in the majority of dogs and cats is blood loss or lack of RBC production.

Blood-Loss Anemia

Blood loss can occur for a variety of reasons in the animal with renal failure. Iatrogenic blood-loss anemia from frequent blood sampling for diagnostic testing is the first consideration for hospitalized animals. The blood volume for diagnostic testing of cats or small-breed dogs should be minimized to limit iatrogenic loss. Other possible sources of blood loss include gastrointestinal bleeding, ectoparasitism or endoparasitism, and uremia-induced defects in platelet function. Animals receiving hemodialysis have mild ongoing RBC loss in the dialysis circuit. Typically blood loss should initiate a regenerative response from the bone marrow; however, animals with chronic kidney disease cannot mount an appropriate regenerative response because of relative erythropoietin (EPO) deficiency. In addition, iron deficiency occurs with prolonged blood loss, which attenuates a regenerative response.

Uremic Gastropathy

Gastric ulceration and necrosis are common findings in humans with chronic kidney disease. Gastric histopathology findings in dogs with renal failure include gastric

edema, vasculopathy, glandular atrophy, mineralization, and submucosal arteritis, with ulceration or necrosis being relatively uncommon findings (Peters et al., 2005). However, clinical experience with animals in renal failure indicates that significant gastrointestinal bleeding occurs in certain patients. Gastrin, a polypeptide hormone produced in the G cells in the stomach, is renally excreted; and cats with chronic kidney disease have increased gastrin levels, although the relationship between creatinine and serum gastrin levels is not linear (Goldstein et al., 1998). Persistent increases in serum gastrin can result in gastric hyperacidity and mucosal erosions. Additional factors that can contribute to gastrointestinal bleeding include concurrent use of nonsteroidal antiinflammatory medications or corticosteroids. Although ongoing blood loss from uremic enterocolitis might contribute to anemia, it would be unlikely for this disorder to represent the sole cause of anemia. Animals with acute renal failure can experience gastrointestinal signs similar to patients affected by chronic kidney disease; however, the relatively short duration of pathologic changes with acute renal failure make blood-loss anemia from gastrointestinal sources a less frequent occurrence.

Clinical signs of upper gastrointestinal bleeding include hematemesis, melena, or hematochezia. Melena is not always seen in animals with chronic gastrointestinal blood loss since loss can occur in relatively small quantities over time. Uremic enterocolitis causes marked large bowel diarrhea with frank blood. Other indicators of blood loss include an elevated blood urea nitrogen (BUN)/creatinine ratio and microcytic, hypochromic anemia when chronic loss has been sufficient to result in iron deficiency.

Increased Bleeding Tendency

The chief hemostatic change that occurs with uremia is impaired platelet function. Total platelet count in animals with renal failure is usually within or slightly below reference range unless the underlying etiology of the renal failure also results in thrombocytopenia (e.g., leptospirosis). Platelet counts typically have to be severely reduced (< 30,000 to 40,000/ μ l) for clinical bleeding to result from thrombocytopenia alone. Prolonged skin bleeding times have been described in humans with renal failure, and prolonged buccal mucosal bleeding time has been reported in dogs with renal failure. Proposed mechanisms for platelet dysfunction in dogs include defective platelet cyclooxygenase causing reduced thromboxane

A2 production, abnormal concentration of large multimers of von Willebrand factor, abnormal intracellular cyclic adenosine monophosphate concentration, and abnormal intracellular calcium mobilization. These changes cause impaired subendothelial adhesion of platelets and abnormal platelet aggregation. Total von Willebrand factor has been found to be normal in dogs with renal failure.

Red Cell Destruction

The uremic environment decreases RBC survival in some humans, but dogs with renal failure had no evidence of increased RBC fragility. Parathyroid hormone has been proposed as a cause of hemolysis, but the evidence is inconclusive.

Decreased Erythropoiesis

Erythropoietin deficiency. EPO is the hematopoietic growth factor that stimulates erythropoiesis in anemia, and deficiency is the most commonly recognized contributor to anemia of chronic kidney disease. Most EPO is produced in the peritubular interstitial cells of the outer medulla and inner cortex of the kidney; however, between 10% and 15% of total EPO is produced by the liver. Renal hypoxemia caused either by anemia or hypoxia is the main trigger for EPO production, and the main effect of EPO is to stimulate RBC growth and differentiation in the colony-forming unit–erythroid cells of the bone marrow. Following an increase of EPO production, a time period of approximately 5 days is required for the release of erythrocytes into the circulation. Additional effects of EPO to benefit the anemic patient includes induction of hemoglobin and RBC membrane protein synthesis and facilitation of RBC release from the bone marrow to the bloodstream. With chronic kidney disease and reduced renal mass, renal EPO production is attenuated, which causes relative EPO deficiency. In anemic dogs with chronic kidney disease, measured EPO can be above normal but not as elevated as in dogs with similarly severe anemia that are not uremic. Cats with chronic kidney disease have EPO levels that are similar to those of normal cats.

Other factors contributing to decreased erythropoiesis.

Humans with chronic kidney disease and poor nutritional status can develop deficiencies of certain vitamins, especially B vitamins. These vitamins, particularly B₁₂ (cobalamin), folic acid, niacin, B₂ (riboflavin), and B₆ (pyridoxine), are all important in erythropoiesis. Although deficiencies have been documented in humans with chronic kidney disease, evaluation of B-vitamin concentrations has not been reported in dogs or cats with chronic kidney disease. Protein-calorie malnutrition can contribute to nonregenerative anemia.

A variety of possible uremic toxins have been identified in humans, and some of these toxins may contribute to poor regenerative response of the bone marrow. The hematologic effects of these substances have not been investigated in dogs and cats.

Iron deficiency can be caused by chronic blood loss and poor iron intake in renal failure. Iron deficiency anemia must be differentiated from anemia of chronic inflammatory disease, which also causes a nonregenerative anemia.

The distinction between these etiologies is important relative to therapy; iron deficiency anemia would be expected to respond to supplemental iron therapy, but anemia of chronic inflammatory disease persists with iron therapy, and iron overdose can result.

DIAGNOSIS

When determining a cause for anemia in the animal with renal failure, specific historical questions to consider include evidence of listlessness, exercise intolerance, hematemesis, melena, hematochezia, and/or recent hospitalization with frequent blood sampling. In addition, reports of a sudden decline in attitude or activity might increase suspicion of acute blood loss either externally or internally. Physical examination can reveal pallor consistent with either anemia or hypovolemia. Examination findings that occur with clinically significant anemia include lethargy, poor responsiveness, tachypnea, tachycardia, weakness, and deviations from normal pulse quality (e.g., bounding or weakly palpable pulses). If a rapid clinical decline was noted historically, hemorrhage into a body cavity may be considered, or melena may be identified by digital rectal examination. Identification of mucosal blood loss, most commonly seen as gingival bleeding, would be consistent with uremic platelet function defect. Profound anemia can result in retinal hemorrhages, although this is seen uncommonly with the anemia of chronic kidney disease.

Complete blood count in the anemic renal failure patient should reveal normocytic, normochromic, nonregenerative anemia. This finding is consistent with the relative EPO deficiency of chronic kidney disease; however, it is also consistent with anemia of chronic inflammatory disease and iron sequestration. White blood cell count, differential, and platelet count are not affected. Any abnormalities in these cell lines should be evaluated as separate problems. A regenerative response (i.e., reticulocytosis, polychromasia, macrocytosis) is not a feature of anemia of chronic kidney disease caused by relative EPO deficiency. These findings are strongly suggestive of blood loss or hemolysis of longer than 5 days' duration. Microcytosis and hypochromasia should be seen in animals with chronic iron deficiency. RBC deformities (echinocytes, burr cells) can occur in uremic patients.

Additional tests may be needed to determine the cause of anemia. If clinical evidence of mucosal bleeding was evident on examination and platelet count was within reference ranges, buccal mucosal bleeding time should be considered to diagnose underlying platelet function defect. Specific testing can be performed to distinguish iron deficiency anemia from anemia of chronic inflammatory disease; however, results are not always straightforward. An iron panel consisting of serum iron (a mobile form of iron), total iron-binding capacity (an indirect measurement of transferrin, the serum carrier molecule for iron), and ferritin (a storage form of iron) can be performed. With iron deficiency anemia, all results would be expected to be low. With anemia of chronic inflammatory disease, serum iron is low, and transferrin is normal to low because of sequestration of iron; however, ferritin levels should be normal or increased. Bone marrow core

biopsy samples can also be evaluated for presence of iron stores in the form of hemosiderin. Evidence of decreased iron stores in the bone marrow would be consistent with true iron deficiency; however, this is a more invasive testing modality, and the core biopsy instrument may not be readily available in general practice. If anemia of chronic inflammatory disease is suspected, appropriate testing to identify the inflammatory disease (e.g., imaging studies, serologic testing) should be performed. Thoracocentesis or abdominocentesis are indicated with historical evidence of acute blood loss and suggestive physical examination findings.

Although EPO deficiency is the most likely explanation for nonregenerative anemia with chronic kidney disease, EPO levels are not typically measured in the clinical setting because of expense and delay in receiving results, and a normal EPO level does not rule out relative EPO deficiency. When all other causes of anemia are ruled out, therapeutic response to EPO is the usual means to identify EPO deficiency.

TREATMENT

Minimize Blood Loss

The mainstays of treatment of anemia associated with chronic kidney disease include minimizing ongoing blood loss and increasing RBC number and production. Hospitalized patients should have blood sampling frequency and volume minimized to what is clinically necessary. For patients less than 4.5 kg (10 lbs), pediatric blood sampling tubes containing anticoagulant appropriate for less than 1 ml of blood can be used to perform most biochemical tests. The clinician should determine if daily monitoring of biochemical values is necessary for treatment decisions; in many cases every-other-day testing of BUN and creatinine is sufficient.

Treatment for endoparasitism or ectoparasitism should be performed if indicated. Gastrointestinal blood loss secondary to uremic gastropathy can be minimized by resolving the uremic crisis and providing gastroprotective drugs. Gastroprotective treatments to consider include histamine-2 receptor antagonists such as famotidine (0.5 mg/kg orally [PO], intramuscularly [IM], intravenously [IV] SID) or ranitidine (1 mg/kg PO, IM, IV, BID), locally acting gastric protectants such as sucralfate (0.25 to 1 g PO TID), or proton pump inhibitors such as omeprazole (0.5 to 1 mg/kg PO SID). These doses reflect a dose reduction for renally excreted drugs such as histamine-2 receptor antagonists. Resolution of anemia and improvement of the BUN:creatinine ratio would be evidence of response to treatment.

Maximize Regenerative Capability

Iron Deficiency

Iron deficiency anemia should be treated with iron supplementation; however, treatment with iron alone does not resolve anemia from EPO deficiency, and treatment of anemia of chronic inflammatory disease with iron does not resolve anemia and can result in iron overdose. If a chronic inflammatory disease has been diagnosed in

addition to chronic kidney disease, specific treatment for the inflammatory disease can be initiated. With true iron deficiency and when recombinant EPO therapy is initiated, oral supplementation with ferrous sulfate (dogs: 100 to 300 mg total daily dosage PO; cats: 50 to 100 total daily dosage PO) is the traditional treatment method. Oral iron therapy can result in gastrointestinal upset in certain individuals. Dividing the daily dosage and administering with food may help to prevent this side effect. Oral iron supplementation is generally insufficient to meet the demands of erythropoiesis in humans receiving EPO therapy; parenteral iron administration is recommended. Serum iron and ferritin decreased and evidence of iron deficiency developed in dogs treated with oral iron supplementation during EPO therapy (Randolph et al., 2004a). Iron dextran (50 mg/cat or 10 to 20 mg/kg/dog IM q3-4 weeks) can be administered by intramuscular injection. A risk of anaphylaxis exists with this treatment when administered intravenously, and iron overdose can result.

Nutritional Status

If malnutrition is considered to be contributing to anemia, calorie and nutrient intake should be optimized. Resolving a uremic crisis can improve voluntary food intake in some animals. Providing a balanced diet for animals with renal impairment can prevent protein-calorie malnutrition and optimize vitamin intake. In humans with renal failure B vitamin supplementation can improve anemia of chronic kidney disease modestly; however, no studies exist on providing supplemental B vitamins to animals in renal failure. If voluntary food intake is inappropriately low, enteral nutrition can be provided by way of a nasoesophageal, esophagostomy, or gastrostomy feeding device (Chapter 196).

Erythropoietin Therapy

Erythropoietin can be used for treatment of anemia in dogs and cats with chronic kidney disease. The only commercially available EPO is recombinant human EPO (r-HuEPO), which has approximately 80% amino acid sequence identity to canine and feline EPO. This degree of variation in sequence homology allows r-HuEPO to be effective in increasing RBC production in dogs and cats, but it also causes the major complication of EPO therapy: anti-EPO antibody formation. Both recombinant canine and feline EPO have been studied in a research setting, but neither product is available commercially (Randolph et al., 2004a; Randolph et al., 2004b.) r-HuEPO is not approved for use in animals by the Food and Drug Administration; therefore clients should sign an informed consent before veterinary use. Although a number of products are currently available for humans, Epogen (Amgen) and ProCrit (Ortho Biotech Products) have been the most commonly used for veterinary applications. Therapy should be reserved until anemia is clinically significant because of the potentially life-threatening nature of anti-EPO antibody formation. The recommended starting dose of EPO is 100 units/kg subcutaneously three times weekly until the packed cell volume (PCV) is at the low end of the reference range (dogs 30% to 35% PCV; cats 25% to 30% PCV). Iron supplementation is imperative with initiation of EPO therapy at doses previously described.

The desired PCV typically takes 4 to 12 weeks to achieve. At this point, dosing interval is reduced to twice weekly until PCV is in the middle of the desired range. Maintenance dosage is typically 50 to 100 units/kg once to twice weekly. The PCV and reticulocyte count should be checked weekly during treatment until four consecutive readings are stable at a specific dose and then monthly thereafter. Overproduction of RBCs can cause polycythemia, hyperviscosity, and hypertension and should be avoided.

Laboratory evidence of anti-EPO antibodies has been reported to occur in 60% to 100% of dogs receiving r-HuEPO; whereas clinically significant anemia has been reported to occur in 20% to 70% of dogs and cats receiving EPO, presumptively as a result of anti-r-HuEPO antibody formation (Cowgill et al., 1998; Langston et al., 2003). Antibodies typically develop within the first few months of therapy but could have a later onset. If anti-EPO antibody formation occurs, the antibodies suppress native EPO action on bone marrow precursor cells, resulting in profound anemia. The primary sign of immunologic reaction is a precipitous decline in PCV following a prior response to therapy. Reticulocyte counts decrease to zero before a decline of PCV. If clinical evidence supports this drug complication in dogs or cats, EPO therapy should be discontinued, and transfusion therapy initiated. Antibody levels can decline and resolve over 2 to 12 months, and PCV can return to the pretreatment level. Although the anemia associated with antibody formation can be reversed, the patient can remain transfusion dependent for weeks to months. The need for multiple transfusions over time causes crossmatch incompatibility even when blood-type compatibility is addressed before transfusion, and incompatibility adds to the cost and complexity of the management of anemia. In addition, the anemia that required EPO therapy initially would still be present following resolution of antibodies. Therefore development of this complication frequently results in death or euthanasia of the animal.

Hypertension is a complication of EPO administration in humans, and blood pressure increases in almost 60% of cats treated with EPO. Blood pressure should be monitored weekly during the initial administration of EPO (Chapter 197). Other reported complications of EPO administration include seizures, vomiting, injection discomfort, skin reactions, cellulitis, cutaneous or mucocutaneous reactions, fever, and arthralgia; but these complications are rare.

Darbepoetin (Aranesp, Amgen) is a derivative of r-HuEPO that has more attached carbohydrate groups to slow clearance and decrease the frequency of administration. The initial regimen calls for weekly injections, which decreases to once every 3 weeks for maintenance therapy in humans. Experimental evidence suggests that it is less likely to cause an immunologic reaction in nonhuman subjects. All antibodies to r-HuEPO described to date are directed against the protein component, and the additional carbohydrate moieties of darbepoetin may shield the protein backbone from immunologic exposure. Experience with this drug is limited in veterinary medicine but promising. It appears to be effective, although apparently at least one dog has developed neutralizing antibodies (personal observation).

Over the last 5 years anti-r-HuEPO antibody formation in humans has been reported with increasing frequency, a condition that had been reported in only three humans before 1998. Extensive evaluations have led many to suspect that the risk of antibody formation is higher with subcutaneous administration compared to the intravenous route, perhaps because of slower clearance with subcutaneous administration. Optimal treatment for this condition in humans is unclear, but immunosuppressive therapy appears helpful.

Future Directions

Virus-vectored feline EPO gene therapy has been investigated and holds some promise, although control of gene expression and distribution is a problem that still must be overcome. Continuous EPO receptor activator has a significantly longer half-life than EPO or darbepoetin and is being investigated in humans. A drug that inhibits enzymatic degradation of hypoxia-inducible factor, a molecule that stimulates EPO production, is being investigated and would not be expected to induce antibody formation.

When to Transfuse?

Transfusion should be considered when RBC mass has declined sufficiently to limit oxygen-carrying capacity and cause clinical signs of anemia and when rapid increase of oxygen-carrying capacity is needed (e.g., before general anesthesia, following development of anti-EPO antibodies). There is no set PCV at which transfusion is always indicated. The decision to transfuse is based on clinical signs (i.e., fatigue, pallor, tachypnea, tachycardia, and weakness) and duration and degree of anemia. Mild-to-moderate reductions in PCV are often tolerated reasonably well in animals with renal failure because of gradual onset, increased levels of 2,3-diphosphoglycerate, and increased cardiac output to facilitate tissue oxygen delivery. In addition, cats in particular are talented at limiting physical activity to tolerate anemia.

Oxygen-carrying capacity can be increased with administration of whole blood or packed RBCs. Risks of blood transfusion include volume overload with rapid administration, acute hypersensitivity reaction, and transmission of infectious disease. Incompatibility reactions can be minimized by accurate blood-typing of donor and recipient in cats, using canine universal donors, and cross-matching for dogs and cats if the recipient has received a prior transfusion (Chapter 56). In addition, the life span of transfused RBCs in a uremic recipient is shortened. The goal for transfusion is to restore the patient PCV to the low end of the normal range to avoid a rapid increase in blood viscosity. If blood products are not available, oxygen-carrying capacity can be increased with administration of a hemoglobin-based oxygen carrier (HBOC) (Oxyglobin, Biopure). This product does not result in increased PCV; patient hemoglobin can be monitored to evaluate response to treatment. HBOCs are strong colloids and must be administered judiciously to prevent volume overload with resultant pulmonary edema or pleural effusion. Cats are more likely than dogs to experience volume overload with this product. The color of the HBOC imparts a red color to the recipient's serum that interferes

with colorimetric tests. This change causes creatinine to be underestimated; however urea nitrogen and electrolytes are measured accurately.

CHAPTER 199

Uncomplicated Urinary Tract Infection

MARY ANNA LABATO, *North Grafton, Massachusetts*

DEFINITIONS

Urinary tract infection (UTI) is defined as the adherence, multiplication, and persistence of an infectious agent in the urinary system. Infection occurs when there is a break in the host defense mechanisms and sufficient numbers of a virulent microbe are allowed entrance. UTIs usually are caused by bacterial organisms; infections often involve bacteria that are normally present in the distal urogenital tract. However, fungi and viruses occasionally are the causative agent.

Uncomplicated UTIs are uniformly caused by bacterial organisms. An *uncomplicated* (or “simple”) infection is one in which no underlying structural, neurologic, or functional abnormalities of the host are known or suspected.

Pyuria refers to the presence of white blood cells (WBCs) in urine. Significant pyuria is defined as finding greater than three to five WBCs per high-power field during examination of urine sediment from a sample collected by cystocentesis. If the urine is collected by urethral catheterization or voiding and has greater than five to 10 WBCs per high-power field, it should be considered significant. Pyuria indicates urinary tract inflammation and is not synonymous with UTI. A number of disease processes result in inflammation of the urinary system without the presence of an infectious agent.

Bacteriuria refers to the presence of bacteria in urine. The presence of bacteria in urine is not synonymous with UTI as it may represent contamination of the urine sample. High bacterial numbers in a properly collected and

cultured urine sample indicate a bacterial urinary tract infection (Table 199-1).

PATHOGENESIS OF URINARY TRACT INFECTION

UTIs are considered common; however, it has been reported that the incidence of a bacterial UTI is 2% to 3% in dogs and less than 1% in cats. Another report indicated that 14% of all dogs will have a bacterial UTI during their lifetime, and that UTI is more common in female dogs (Chew and Kowalski, 2001). In cats bacterial UTIs occur more often in older animals (>10 yrs old). By comparison, during any given year, 11% of women report having a UTI.

Most UTIs are caused by ascending migration of pathogenic organisms from the distal urogenital tract. Normally a population of bacteria residing in the lower urogenital tract serves as a defense mechanism to prevent colonization of a pathogenic organism; these resident bacteria may emerge as uropathogens if other host defenses are altered. There are a number of other natural and acquired host defenses of the urinary tract. For example, the act of normal micturition is a host defense; it entails frequent and complete voiding of adequate urine volume. A number of anatomic structures serve as defense mechanisms, including a high-pressure zone within the urethra, surface characteristics of the urothelium, and urethral peristalsis. In addition, the length of the urethra may provide protection against ascending

cfu/ml, Colony-forming units per milliliter of urine.

infection. In male dogs prostatic secretions contain immunoglobulins and antibacterial components. Upper urinary tract host defense mechanisms include an extensive renal blood supply and flow, ureterovesical flap valves, and ureteral peristalsis. There are a number of mucosal defense barriers within the urogenital tract. These are comprised of antibody production, the surface layer of glycosaminoglycans, and intrinsic mucosal antimicrobial properties. Equally important are the rapid turnover and exfoliation of urothelial cells. Normal urine also has antimicrobial properties. Urine pH (high and low ranges), hyperosmolality, Tamm-Horsfall mucoproteins, and high concentrations of urea and organic acids impede bacterial growth.

The organisms that commonly cause UTI in dogs and cats are similar. Infections caused by *E. coli* are most common. Gram-positive cocci are the second most common isolates (enterococci, staphylococci, and streptococci). *Proteus*, *Klebsiella*, *Pasteurella*, and *Pseudomonas* are also frequent isolates. Most UTIs are the result of ascending infections from the distal urogenital tract. The bacteria must gain access to the urinary tract and adhere to and colonize the urothelial surface. Infection depends on the number and virulence of the organism and the interaction with the host defenses. Fortunately most acute lower UTIs are uncomplicated and are not associated with signs or symptoms of upper UTIs. UTI or prostatitis is uncommon in male dogs. Acute or chronic prostatitis should be considered a complicated infection and treated accordingly. It is equally important to rule out underlying causes for the infection (e.g., hyperadrenocorticism, prostatic neoplasia, benign prostatic hypertrophy).

CLINICAL FINDINGS

Dogs and cats with UTI may or may not demonstrate signs of urinary tract disease. The development of clinical signs depends on the site and duration of infection, the presence or absence of predisposing causes, the body's compensatory response, and the virulence and numbers of the uropathogen. Lower tract UTIs may present with pollakiuria, stranguria, dysuria, hematuria, and inappropriate urinations. The bladder and proximal urethra are so closely associated that inflammation in one is thought to affect the other. Female dogs with abnormalities of the

vulva, perivulvar dermatitis, or vaginal stenosis may have an increased risk of UTI. Gross hematuria at the beginning of urination or a urethral discharge may be associated with urethral or prostatic disease. Prostatic disease is a more common cause of urethral discharge independent of urination than is urethral disease. Differential diagnoses for dysuria, pollakiuria, and hematuria consist not only of bacterial cystitis but include cystic calculi, neoplasia, detrusor overactivity ("urge incontinence"), prostatitis, idiopathic or interstitial cystitis in cats, and urethritis. Clinical signs associated with upper urinary tract involvement may include fever, pain, hematuria, septicemia, polyuria or renal failure.

Historical or clinical findings that would lead a UTI to be classified as *complicated* include recurrence, persistence in the face of appropriate treatment, or the presence of host abnormalities (e.g., hyperadrenocorticism or corticosteroid administration, diabetes mellitus, renal failure, neurogenic bladder dysfunction).

DIAGNOSIS

Diagnosis should be based on urinalysis, urine culture, and antimicrobial susceptibility testing. The urine sample should be obtained in a sterile manner, preferably by cystocentesis. Urine culture with sensitivity is a valuable diagnostic tool even in the first-time, uncomplicated infection. Quantification of bacterial numbers helps to identify contamination (collection via free-catch or manual expression) versus true infection. Once bacterial identification is determined, selection of the appropriate antibiotic makes treatment efficient and economical. If infection recurs, prior urine cultures also help determine whether the "new" infection is a relapse of the initial infection or reinfection with a different organism. Additional testing ideally should include a complete blood count, chemistry profile, and some form of diagnostic imaging (survey radiographs, abdominal ultrasound, or contrast radiography). Quite frequently, especially in cats or immature dogs, it is difficult to obtain a sterile urine sample. The bladder may be too small to safely obtain a sample as a result of the pollakiuria, or the animal may be too uncooperative to safely restrain without sedation. In these cases the presumptive diagnosis of UTI is made based on history, clinical signs, physical examination, and response to treatment.

The Minimum Inhibitory Concentration

It is important to understand the meaning of culture and susceptibility results to select the ideal antimicrobial agent. The minimum inhibitory concentration (MIC) is the lowest drug concentration that inhibits microbial growth (this does not necessarily mean all bacteria are killed outright). In vitro MIC cannot be interpreted as absolute values since they are based on the ability of the drug to reach a given concentration in plasma. Plasma and urine concentration may vary in an individual patient for many reasons. The criteria for categorizing bacteria as *susceptible*, *intermediate*, or *resistant* to a given antimicrobial plasma concentration are based on knowledge of the predictable susceptibility of the organism and on another dilution, the *breakpoint value*. The breakpoint is an arbitrary criterion, generally set at the point at which the majority of all isolates for that microbe are inhibited, and should be provided by the veterinarian's microbiology laboratory. These data are obtained from thousands of cultures and sensitivities and are determined by a regulatory agency, the National Committee for Clinical Laboratory Standards (NCCLS). Knowing the breakpoint is a key step in choosing the appropriate antibiotic. The farther the MIC of an individual organism is from the breakpoint, the more likely a drug is to be effective. For example, *E. coli* is cultured from a urine sample. The organism is sensitive to cephalexin with an MIC of 2 mcg/ml. This is four dilutions away from the breakpoint of 32 mcg/ml. It is also sensitive to trimethoprim-sulfa with an MIC of 40 mcg/ml, only one dilution away from the breakpoint of 80 mcg/ml. Assuming that all other factors are equal, the chance of successful treatment is greater with cephalexin than trimethoprim-sulfa.

As a general rule, one should avoid choosing a drug when the MIC is approaching the breakpoint (often reported as "intermediate" susceptibility). If the only antimicrobial choice is a drug with an MIC near the breakpoint, the antimicrobial dose selected should be in the high end of the dosing range. If an antimicrobial is cleared through the kidney and reaches a high concentration in

urine, even a drug with an intermediate sensitivity may be effective in treating the infection. Antimicrobials categorized as "resistant" for an organism do not inhibit the organism at the usual blood or tissue concentrations and are unlikely to be effective.

TREATMENT

Treatment of an uncomplicated lower UTI should resolve during a 7- to 10-day course of antibiotics. If an upper tract infection is suspected or definitively diagnosed, treatment should continue for a minimum of 4 weeks. In human medicine it is recommended that a simple, uncomplicated infection be treated for 3 days and acute uncomplicated pyelonephritis for 14 days. More studies are needed in veterinary medicine to establish optimum length of therapy for dogs and cats. Clinical signs should resolve within 48 hours of starting treatment.

If culture results are available, antimicrobial choice should be based on the susceptibility as described previously. Treatment of an uncomplicated infection may be undertaken without culture results if this is an initial infection and the patient has not received antibiotics within the last 4 to 6 weeks. In these cases the choice of antibiotics should be based on the knowledge of the bacteria most commonly causing UTI (Table 199-2). Gram stain of urine sediment may provide an indication regarding the type of organism causing the infection and guidance about which antibiotic to use. As stated previously, the most common isolate is *E. coli*, which is a gram-negative rod associated with an acidic urine. Staphylococci are gram positive and associated with alkaline urine because they produce urease.

When instituting empiric therapy, a broad-spectrum antibiotic should be the first choice (Table 199-3). Cephalosporins usually have activity against both *E. coli* and *Staphylococcus* spp. Another alternative is trimethoprim-sulfa. Drugs related to penicillin should also be considered. The use of fluoroquinolones for the empiric treatment of UTIs is contraindicated because of the inherent resistance of many gram-positive bacteria

Table 199-2

Antimicrobial Selections for Common Urinary Tract Pathogens

Organism	Drug	Alternative
Gram-Negative Organisms		
<i>Escherichia coli</i>	Cephalexin Trimethoprim-sulfonamide	Fluoroquinolone
<i>Proteus</i> spp.	Ampicillin Amoxicillin-clavulanate	Cephalexin
<i>Klebsiella</i> spp. <i>Pseudomonas aeruginosa</i>	Cephalexin Fluoroquinolone	Trimethoprim-sulfonamide Tetracyclines
Gram-Positive Organisms		
<i>Staphylococcus</i> spp.	Ampicillin Amoxicillin-clavulanate	Cephalexin
<i>Streptococcus</i> spp.	Ampicillin Amoxicillin-clavulanate	Cephalexin
<i>Enterococcus</i> spp.	Trimethoprim-sulfonamide	Fluoroquinolone

Table 199-3

Guidelines for Antibiotic Usage for Urinary Tract Infections

Drug	Recommended Dosage
Ampicillin	25 mg/kg q8h PO
Amoxicillin-clavulanate	15 mg/kg q12h PO
Cephalexin	22 mg/kg q8h PO
Doxycycline	5 mg/kg q12h PO
Enrofloxacin	5 mg/kg q12h PO
Trimethoprim-sulfa	15 mg/kg q12h PO

and the development of resistance patterns in many gram-negative organisms, especially *E. coli*, to this class of antibiotics. After the completion of the course of antibiotics, it is preferable to perform a urine culture to ensure that the infection has been resolved. The culture should be obtained at least 4 to 5 days after completion of the course of therapy. If antimicrobial treatment does not result in sustained clinical response and negative urine culture, further investigation of owner compliance and host defenses is indicated.

CHAPTER 200**Multidrug-Resistant Urinary Tract Infection**

JEANNE A. BARSANTI, Athens, Georgia

Urinary tract infections (UTIs) are common in dogs and in geriatric cats. Most are caused by common bacterial organisms and easily treated successfully with short (7 to 10 days) courses of commonly available antibiotics. However, some UTIs are difficult because infection recurs frequently. Multidrug-resistant organisms cause approximately 30% of such difficult UTIs (Sequin et al., 2003). A case from a private practice is presented to illustrate the important concepts in dealing with difficult UTIs.

CASE EXAMPLE

A 12-year-old, female, spayed, mixed-breed dog weighing 9 kg was presented for hematuria, dysuria, and licking

the vulva. The client owned this dog for 1 year. The previous owner told the client that the dog had been licking its vulva on occasion for the past 2 years. Hematuria and dysuria were new problems. The dog appeared to be normal on physical examination, so the veterinarian prescribed a quinolone antibiotic without doing a urinalysis or culture. The dog did not improve. On the second presentation a cystocentesis urine sample was submitted for culture. The result was a hemolyzing *E. coli* (>100,000 colony-forming units [CFU]/ml). The organism was reported to be sensitive only to nitrofurantoin and imipenem. Nitrofurantoin was prescribed at 4 mg/kg every 8 hours for 4 weeks. The dog's clinical signs resolved, and a complete urinalysis performed during therapy was normal.

Within 3 days of discontinuing therapy, the dog's clinical signs returned. A culture of urine collected by cystocentesis again revealed hemolyzing *E. coli* (>100,000 CFU/ml) with the same sensitivity pattern. A third-generation cephalosporin that was not on the sensitivity panel was administered subcutaneously once a day for 4 weeks. Again clinical signs resolved, and a complete urinalysis performed during therapy was normal with no bacteria seen. Within 1 week of discontinuing therapy, clinical signs returned, and culture revealed hemolyzing *E. coli* with the same sensitivity pattern. Imipenem was used intravenously three times a day for 2 weeks.

Ten days after stopping therapy clinical signs returned, and urine culture results were the same as on previous occasions. A complete blood count (CBC) and serum biochemical profile were normal. An adrenocorticotrophic hormone response test suggested hyperadrenocorticism, which was controlled with trilostane. After controlling the hyperadrenocorticism, the third-generation cephalosporin was used subcutaneously for 6 weeks, and again the dog's UTI returned within 1 week of discontinuing therapy. Radiology and ultrasound of the urinary tract were normal except for an equivocal increase in renal echogenicity. Cystoscopy was performed, and the only abnormality was inflammation around the openings of both ureters, which was confirmed by histopathology. The vagina, urethra, and rest of the bladder mucosa appeared to be normal. This is a frustrating, difficult UTI for the dog, the owner, and the veterinarian.

DIAGNOSTIC APPROACH

This case is an example of recurrent UTI. The first diagnostic step in such a case is to differentiate *relapse* from *reinfection*. A relapse is a UTI caused by the same organism that recurs after therapy is discontinued. Although most relapsing UTIs recur quickly, some do not relapse for months (Freitag et al., 2006). When recurrence of a UTI with the same organism does not occur for months, it is difficult to distinguish a relapsing infection from a reinfection caused by the same organism, perhaps derived from the gastrointestinal tract. A reinfection is generally defined as a UTI caused by a different organism that recurs at variable intervals after therapy is discontinued. Less common types of difficult UTIs are persistent infections and superinfections. Distinguishing between these types of UTIs requires performing urine cultures before, during, and after therapy.

Relapsing Infections

Distinguishing relapses from reinfections is difficult because one must determine whether the organism is the same or different. If the species type changes (e.g., from *Proteus* to *E. coli*), the decision is simple. However, *E. coli* is the most common cause of UTIs and there are many varieties of *E. coli*. Clinicians have relied mainly on the sensitivity pattern of the organism to help determine whether the current infection is caused by a new or the same *E. coli*. However, the same *E. coli* can shift in regard

to antibiotic sensitivity; thus this method is not very accurate (Drazenovich, Ling, and Foley, 2004; Freitag et al., 2006). Unfortunately more accurate methods such as pulsed-field gel electrophoresis are not readily available. The UTI in the example case fits a relapsing infection best: the infection recurs rapidly with discontinuation of treatment, and the organism is the same type with the same antibiotic sensitivity pattern. This is an important determination since the pathophysiology of relapsing infections differs from that of reinfections.

In relapsing infections the problem is usually that the organism has found a deep-seated niche in the urinary tract, protected from antimicrobial action. The antimicrobial kills the bacteria that are in the urine but cannot reach those deep in tissue sites. The likely tissue sites are the kidney (chronic pyelonephritis) and the prostate gland in intact males. Struvite uroliths are another potential site of infection. Other sites are the submucosa of the bladder and any location associated with a partially obstructive process such as a ureterolith. Experimentally it has been found that uropathogenic *E. coli* can enter host bladder epithelial cells and remain quiescent for a period of time before leaving the cell and replicating again (Mulvey, 2002; Schilling, Mulvey, and Hultgren, 2001).

The appropriate diagnostic approach in a relapsing UTI is finding the site where the bacteria are hiding. This involves imaging the entire urinary tract, as well as evaluating prostatic fluid in intact male dogs. The example case is typical of relapsing infections: the infection appears to respond to antibiotics because the clinical signs are secondary to bacteria from elsewhere in the urinary tract entering the bladder and resulting in signs of cystitis. When antibiotics effective against the organism are administered, the bacteria in the urine are killed, and the cystitis abates. Not all relapsing UTIs are associated with clinical signs. Some recur and remain silent, detected only by repeated urine cultures. The veterinarians in the example case tried to determine the site of infection. They found that the most likely site was the ureters/kidneys because the cystoscopy found chronic inflammation around the ureteral orifices and the ultrasound suggested increased renal echogenicity. An excretory urogram would also be indicated to evaluate the kidneys and ureters more fully.

Reinfections

With reinfections, the problem is not curing the infection. In this instance each infection is cured. However, the pet becomes reinfected with a different organism at a variable interval. The causes are multiple and include poor systemic immune function (such as hyperadrenocorticism or immunosuppressive drug therapy), loss of one of the antimicrobial properties of urine (such as glucosuria associated with diabetes mellitus or poor urine-concentrating ability from any one of many causes), an anatomic predisposition to infection (such as a stricture, a urolith, a prior urethrostomy, or a neoplasm), or a physiologic predisposition to infection (such as urine retention from a neurologic problem or decreased urethral sphincter tone). Diagnostic tests should include physical examination of

the vulva or prepuce, palpation of the urinary tract and prostate gland, CBC, serum biochemical profile, complete urinalysis, urinary tract imaging, and determination as to whether the pet can empty the bladder normally. In some cases, especially female dogs, all of the above are normal. For example, almost 30% of 100 dogs in one retrospective study had no identifiable underlying reason for reinfections (Sequin et al., 2003). I have assumed that such dogs have a defect in local immunity, allowing bacteria to adhere to the reproductive and urinary tract mucosa and make their way to the bladder.

Persistent Infections

A persistent infection is one in which the original causative bacteria continue to be present during therapy that should be effective based on culture and sensitivity. Such infections can be diagnosed only by performing a urine culture during therapy to document that bacteriuria continues. A common misconception is that urine cultures of animals given antimicrobials will always be negative. This is correct only if the drug is effective, as is true in most UTIs because of high concentrations of antibiotics in urine. However, if the organism is resistant to the drug chosen for therapy, bacteria grow despite the presence of the drug. Persistent UTI is a very difficult situation and fortunately rare. Usually a persistent infection indicates that there is a failure of host defense mechanisms. There may be a structural abnormality in the urinary tract that must be corrected to resolve the infection. The causative organism is often highly antibiotic resistant or unusual. It is also possible that the drug administered is not getting into the urine at antibacterial concentrations. How the prescribed drug is metabolized and excreted should be reviewed. The possibility that the drug is not being administered by the client should also be considered by asking the client how he or she is giving the medication and how he or she knows that the pet ingests it. If client and patient compliance are not issues, the diagnostic approach must include a serum biochemical profile to evaluate liver and kidney function. Urinary tract imaging should be performed to find any underlying structural problem.

The veterinarians in the example case performed a complete urinalysis during therapy to confirm drug efficacy and rule out persistent infection. A urine culture would have been useful to confirm the urine cytology since bacteria can be present in urine and difficult to detect by cytology unless Wright's stained smears are used (Swenson et al., 2004). Although a urine culture was not performed in the example case to completely exclude a persistent infection, the facts that urinalyses performed during therapy were normal and that clinical signs resolved with therapy support the conclusion that the infection was not persisting during therapy.

Superinfections

A superinfection is an infection with a different organism that arises during the course of treatment for the original organism. A superinfection can be diagnosed only

by doing a urine culture during therapy. Superinfections usually are associated with indwelling urinary tubes.

THERAPEUTIC APPROACH TO RECURRENT INFECTIONS

Even difficult UTIs usually are caused by aerobic, common bacterial organisms. Unfortunately the most common organism, *E. coli*, is highly diverse with the ability to develop multidrug resistance (MDR). One recent pilot study in dogs showed that MDR developed within 3 days of treatment with amoxicillin or enrofloxacin (Debavalya et al., 2007). Although MDR resolved within 3 weeks after treatment with amoxicillin, MDR did not resolve after treatment with enrofloxacin. In the example case a quinolone was used without doing a urine culture. On the first culture the *E. coli* was resistant to multiple drugs. Without an initial urine culture, it is impossible to know whether quinolone therapy induced MDR or whether the organism was originally resistant. This emphasizes the importance of doing urine cultures before therapy, especially when using a quinolone, which generally should not be used as first-line therapy. If the bacteria identified exhibit MDR, many laboratories will do extended antimicrobial testing on request.

Relapsing Infections

The goal with relapsing infections is to find the site and determine if any predisposing factors at that site can be corrected. For example, if a chronic prostatic infection is found, neutering assists in elimination of infection. In the example case hyperadrenocorticism was present, but controlling the hyperadrenocorticism did not help with treatment of the UTI. It is possible that the infection occurred independently of that condition or was firmly established before the hyperadrenocorticism was controlled. It is not recommended to remove kidneys affected by pyelonephritis since nephrectomy rarely results in control of UTI (both kidneys are often affected). Because the site of infection should not be removed and since it is very difficult for antimicrobial agents to penetrate and act effectively in the renal medulla, prognosis for cure of chronic pyelonephritis is always guarded. A similar prognosis appears warranted for dogs with nephroliths and recurrent upper-tract UTIs because complete elimination of the nephroliths and clearance of accompanying deep-tissue infection is difficult in many cases. The example case illustrates these frustrating facts well. The drugs were not failing to kill the organism; they were failing to reach the primary site of infection. Few antibiotics are thought to penetrate renal tissue: trimethoprim, chloramphenicol, nitrofurantoin, some of the quinolones, and the aminoglycosides. Aminoglycosides are not recommended in chronic pyelonephritis because of nephrotoxicity with long-term use. Optimal duration of therapy is unknown, but generally 4 to 6 weeks is recommended. In the example case it may have been better to extend the duration of treatment with nitrofurantoin to 2 to 3 months since it seemed to control the UTI without adverse effects. One must consider potential drug toxicity when using an antibiotic for longer than

normal periods of time. When a case with a relapsing infection appears to have responded to therapy (negative urine culture after therapy completed), it is important to reculture the urine at 1 month and then every 3 months for at least a year to detect another recurrence.

When up to 3 to 6 months of full-dose therapy fails to prevent relapse, one can use suppressive therapy. There is some evidence that in difficult cases in dogs in which no underlying abnormality can be corrected, low-dose, long-term antimicrobial regimens can assist in UTI control (Sequin et al., 2003). This involves administration of a single dose of the effective antimicrobial once a day. The dose is the usual single dose of the drug chosen. If the animal is confined at night, administration after the last urination of the day is recommended so that the urine contains the antimicrobial for the night. This should be started when the infection is under control (negative urine culture). Drugs typically considered for suppressive therapy are trimethoprim, nitrofurantoin, cephalexin, and enrofloxacin. All of these drugs can be potentially toxic. In the example case nitrofurantoin would be a reasonable choice since it was effective at full-dose therapy. Neurologic and hepatic toxicity are possible with nitrofurantoin. Risks of suppressive therapy are induction of antibiotic resistance and/or drug toxicity. The alternative is not treating the infection unless clinical signs are apparent. The risk is that the infection will become systemic. Urine should be cultured monthly during suppressive therapy to ensure that the drug continues to be effective.

Reinfections

An effort should be made to eliminate the underlying predisposing factor. Each infection should be treated for 7 to 10 days in spayed female and neutered male dogs and in cats. Intact male dogs should be treated for 3 to 4 weeks and neutered because of the risk of prostatic infection. Drug choice should be based on urine culture and sensitivity. In intact male dogs an antimicrobial with prostatic penetrance such as trimethoprim, chloramphenicol, or a quinolone should be considered if the organism is reported sensitive. Unless clinical signs are severe, one can wait for these results before prescribing therapy.

If infections recur frequently (more than 4 to 6 times a year), prophylactic (preventive) therapy can be considered. Prophylactic therapy is defined as the administration of an antimicrobial drug to prevent establishment of infection in uninfected sites. Before beginning prophylactic therapy, the current infection should be eliminated with standard full-dose therapy, and then once-a-day therapy begun with a drug to which the organism was sensitive. A urine culture should be performed at the end of full-dose therapy to ensure that the infection was controlled. The chosen drug is given once a day just before a 6- to 12-hour period when urine will be retained in the bladder such as at night in house dogs. The dose is the usual single dose of the drug chosen administered for 6 months in an effort to break the cycle of infections. Urine should be cultured once a month during prophylactic therapy to ensure that UTI is prevented. If

the urine remains sterile for 6 months, the drug is discontinued, and the animal monitored for recurrence. The risks of preventive therapy are the development of antibiotic resistance and drug toxicity. Therefore this approach should be used only if the underlying cause of reinfections cannot be determined or eliminated and if the frequency of reinfections is every few months. It should be noted that there is only anecdotal evidence and one study with a small number of cases to support the effectiveness of this approach in dogs (Sequin, 2003). A recent study of a large number of children indicated that prophylactic therapy did not reduce risk of reinfection but did increase the chance that a second infection would be antibiotic resistant (Conway et al., 2007). Therefore further evaluation of this approach in pets is warranted.

There is some evidence that cranberry juice is helpful in women with frequent reinfections but no such evidence in dogs. The mechanism of action is prevention of bacterial adherence to reproductive and urinary lower tract mucosa. One can use cranberry juice in conjunction with prophylactic antimicrobial therapy, although efficacy is questionable.

Persistent Infections

The first goals with persistent infections are to find and correct any underlying predisposing factors and to question the owner to insure the drug is actually administered. If no cause for treatment failure can be found or corrected, the goal is to find a drug that will work by using measurement of the minimum inhibitory concentration (MIC) of each antimicrobial for that organism and comparing that concentration to concentrations of the antimicrobial in urine (see also Chapter 199). The potential efficacy of each drug is estimated by multiplying the MIC by 4. If the product is less than the mean urine concentration for that drug, it is likely the drug will be effective in killing the bacteria in the urine (though not necessarily in tissue sites) (Bartges, 2005; Polzin, 2006). This assumes that the pet has normal urine concentrating ability. If it does not, the MIC should be compared to serum concentrations of that drug. Once a potentially effective drug is identified, that drug should be started, and urine recultured in approximately 1 week. If the urine culture is negative, the duration of time to use the drug should be based on its safety and the reversibility of the underlying condition.

Superinfections

If possible, the urinary tube should be removed. If this is not possible and the animal is asymptomatic, antimicrobial therapy should be stopped. Antiseptics can be used systemically (e.g., methenamine mandelate) or locally (e.g., Tris-ethylenediaminetetraacetic acid) until the tube can be removed. If the animal has localized symptoms, urinary antiseptics should be tried first. Antimicrobial therapy should be dictated by culture and sensitivity and used if systemic signs of infection develop.

SUMMARY

Urine cultures are an essential component of diagnosing and effectively treating recurrent UTIs. One must differentiate relapsing infections, persistent infections, reinfections, and superinfections to determine appropriate therapy. It is important to look for underlying factors that predispose to recurrent infections and eliminate these for therapy to be effective (Sequin, 2003). The search for such underlying factors involves history; physical examination of the urinary and reproductive tracts; hematology and biochemical laboratory testing; urinalyses; and urinary tract imaging via radiography, ultrasonography, and endoscopy. Antibiotic therapy should be carefully chosen based on antibiotic sensitivity testing and knowledge of antimicrobial metabolism and excretion, toxicity, and ability to reach tissue sites of infection. It is also very important to discuss the need for diagnostic testing and the requirements of potential therapy with the client to be sure the client is able to comply with recommendations.

CHAPTER 201

Cancer and the Kidney

BARRAK M. PRESSLER, *West Lafayette, Indiana*

PPrimary renal neoplasia is extremely uncommon in dogs and cats. Excluding lymphoma, published case series and reviews suggest that primary renal tumors account for 0.6% to 1.7% of all neoplasms in dogs and 1.6% to 2.5% in cats. Retrospective review of cases evaluated by the Oncology Service at North Carolina State University (NCSU) over an 18-year period revealed an incidence of 1.5 cases referred for treatment of renal neoplasms (including renal lymphoma) per year, comprising 0.4% of all patients presenting to this service (unpublished data). This chapter reviews the differential diagnoses for renomegaly and provides an overview of the various subtypes of primary renal neoplasia. Paraneoplastic syndromes associated with renal cancer, the effects of extrarenal tumors on the kidney, and the effects of chemotherapy on the kidney are also reviewed.

RENOMEGALY

Normal Renal Size

In dogs and cats kidney length and volume are linearly correlated to body weight. The right kidney is usually slightly larger than the left, and males have larger kidneys than females; however, these differences are small enough to be clinically irrelevant. Palpation of the kidneys in dogs is difficult; thus renomegaly typically is detected on physical examination only when severe. On the contrary, subtle increases in kidney size may be detected earlier in cats because of the ease of palpation of the kidneys. Normal kidney length in dogs can be approximated by the formula:

$$\text{Kidney length in centimeters} = (0.07 \times \text{body weight in kilograms}) + 4.75$$

but the standard deviation from this result is relatively large, particularly in small- and giant-breed dogs (Barr, Holt, and Gibbs, 1990). On survey radiographs the kidney length is usually between 2.5 and 3.5 times the length of the L₂ vertebra in dogs, and in cats it is between 2.4 and 3 times the same measurement. Although results obtained using this technique correlate well with actual kidney length in most dogs, the large degree of dog-to-dog variations in kidney size makes this comparison only suitable for approximations; thus it should not be used as an inflexible reference range for kidney size. Contrast studies may improve visualization of the kidneys and thus facilitate more exact measurement of length; measurements after contrast administration are slightly longer than those made using plain survey radiographs. Ultrasonography is necessary for measurement of kidney volume and can also be used to measure kidney length.

Differential Diagnosis

Renomegaly may be unilateral or bilateral, symmetric or asymmetric. The most common causes of renomegaly are listed in Box 201-1, as well as the relative expected change in renal size (mild to moderate or severe) and species affected. Primary renal neoplasia is the most common cause of renomegaly in dogs. Common causes of renomegaly in cats include renal neoplasia (particularly lymphoma), granulomatous infiltration (caused by feline infectious peritonitis), perinephric pseudocysts, hydronephrosis, and polycystic kidney disease. Focal renal lesions (such as tumors, intraparenchymal cysts, or abscesses) do occur but rarely cause clinical signs unless they have resulted in distortion of the entire organ. Most focal lesions are incidental findings discovered during diagnostic imaging of the abdomen for another purpose.

Box 201-1	
Causes of Renomegaly in Dogs and Cats*	
UNILATERAL RENOMEGALY	BILATERAL RENOMEGALY
Moderate-to-severe	Moderate-to-severe
• Primary renal neoplasia (C, D)	• Primary renal neoplasia (C, D)
• Hydronephrosis (C, D)	• Hydronephrosis (C, D)
• Lymphoma (C, D)	• Feline infectious peritonitis (C)
• Perinephric pseudocyst (C)	• Lymphoma (C, D)
Mild	• Perinephric pseudocysts (C)
• Compensatory hypertrophy (D)	• Perirenal abscesses (C, D)
• Solitary cysts (D)	• Polycystic kidney disease (C)
• Glomerulonephritis (C, D)	Mild
Variable	• Acute pyelonephritis (C, D)
• Renal abscess (C, D)	• Amyloidosis (D)
	Variable
	• Acromegaly (C)
	• Acute renal failure (C, D)
	• Portosystemic shunts (D)

*The most common causes of renomegaly are in bold type.
C, Cat; D, dog.

Determining whether renomegaly is unilateral or bilateral is usually the first step in narrowing the differential diagnosis list and prioritizing diagnostic tests. Diagnostic imaging, particularly ultrasonography, is usually sufficient to diagnose polycystic kidney disease, hydronephrosis, and perinephric pseudocysts. Diseases that cause distortion of the renal parenchyma such as primary renal neoplasia, lymphoma, or feline infectious peritonitis may require cytologic or histopathologic examination for definitive diagnosis. Other causes of diffuse, mild, bilateral renomegaly, including acute pyelonephritis, amyloidosis, acute renal failure, or portosystemic shunting (in dogs), should be suspected based on concurrent clinical and clinicopathologic findings.

RENAL NEOPLASIA

Detection of a hyperechoic or isoechoic mass effacing normal renal architecture is highly suggestive of renal neoplasia. Histologic determination of the tumor type is required for accurate prognosis and to guide treatment. Although ultrasound-guided percutaneous biopsy can be considered, in the absence of metastatic disease nephrectomy is usually preferred since this may be curative and decreases the risk of iatrogenic seeding of tumor cells. Clinicians should perform careful assessment of renal function before complete nephrectomy. Serum creatinine is an insensitive indicator of kidney disease; determination of glomerular filtration rate should be considered in some cases (Chapter 189).

Renal Cell Carcinomas

Renal cell carcinomas (RCCs) are the most common primary renal neoplasms in dogs, and in cats they are second in frequency only to primary renal lymphoma (Henry et al., 1999; Klein et al., 1988). In published reports RCCs account for 74% to 85% of nonlymphoma primary renal tumors in dogs and cats and have accounted for 59% of all renal tumors in dogs (including lymphoma) presenting to the NCSU Oncology Service; no cats with primary renal carcinoma were evaluated at NCSU during the same time period. Median age of affected animals is 9 to 11 years. In humans there is a moderate increase in risk of RCC for males, a predilection that may exist in dogs as well (Klein et al., 1988). RCCs usually are clinically occult until they have (1) become large space-occupying masses, (2) metastasized and caused other organ dysfunction, or (3) elaborated sufficient cytokines to cause systemic (paraneoplastic) illness or cachexia (Fig. 201-1). In both dogs and cats owners typically seek veterinary care for nonspecific signs such as lethargy, anorexia, and weight loss (Henry et al., 1999; Klein et al., 1988). Less common clinical findings include hematuria, abdominal pain, palpable abdominal mass, or signs associated with renal failure. Azotemia and uremia typically only occur when both kidneys are affected or when neoplasia develops in a patient with preexisting renal disease. Clinicopathologic abnormalities are absent in most dogs with RCCs; but anemia, polycythemia, hypoalbuminemia, leukocytosis, or abnormalities secondary to renal failure may be present (Klein et al., 1988).

Fig. 201-1 Unilateral renal cell carcinoma (longitudinally sectioned) from an 11-year-old Siamese cat. The mass has displaced most of the normal renal parenchyma and caused a moderate amount of subcapsular hemorrhage. As is typical for renal tumors, despite the advanced nature of this neoplasm the cat presented with only vague clinical signs of anorexia and lethargy, and moderate renomegaly was detected on physical examination. No clinical signs referable to disease of the urinary tract disease were reported by the owner; and complete blood count, serum chemistry panel, and urinalysis were unremarkable.

Clinical experience suggests that ultrasonography has high sensitivity and reasonable specificity for diagnosis of primary renal neoplasms. Plain film radiography is less accurate for identification of masses and for confirming that masses are renal in origin, although contrast studies may improve detection. Computed tomography and magnetic resonance imaging have not been evaluated systematically in veterinary patients but are considered superior to ultrasonography in humans. In dogs and cats with renal tumors metastasis usually has occurred at the time of initial diagnosis, most often from delayed diagnosis rather than tumor aggressiveness. The most common sites of metastasis are the regional lymph node, liver, and contralateral kidney; the central nervous system (including the spine, spinal cord, and brain); and lungs (Klein et al., 1988). Local extension may involve the ipsilateral adrenal gland and abdominal serosal surfaces.

Histologic subclassification of RCCs has not been evaluated extensively in dogs and cats. In humans RCCs are subdivided into four main categories, which differ in etiology and prognosis (Moch et al., 2000; Renshaw 2002). Clear cell carcinomas (CCCs, more recently referred to as conventional carcinomas) comprise 75% of cases of renal carcinomas in humans and are so named because many tumor cells have clear cytoplasm. CCCs are thought to arise from renal proximal tubular epithelial cells. There is a strong association between CCCs and deletion or inactivation of the von Hippel-Lindau gene, a tumor suppressor gene that regulates hypoxia-inducible factors and the absence of which results in dysregulated vascular endothelial growth factor expression (Rathmell, Godley, and Rini, 2005). Other subtypes of RCC are papillary RCC, chromophobe RCC, and collecting duct RCC; differentiation and subtype classification of RCCs in humans may

require immunohistochemistry, most commonly using antivimentin, anticytokeratin 7, and anti-RCC marker antibodies (Renshaw, 2002). Likewise there is variation in histologic types of RCC in dogs and cats—tubular, papillary, tubulopapillary, and solid/undifferentiated forms have been reported, with the tubular subtype predominating (Henry et al., 1999).

Nephrectomy is the treatment of choice for solitary renal tumors without azotemia or evidence of metastasis. Partial nephrectomy is often performed in humans and can be considered in dogs and cats if complete excision appears feasible. However, the majority of tumors in veterinary patients are locally extensive by the time of diagnosis, and total nephrectomy usually is required. Unfortunately there are no standardized adjuvant chemotherapy protocols for RCC, and these tumors appear to respond poorly to most agents. Doxorubicin and cisplatin are often administered, but reports of efficacy are lacking. Immunotherapy with interferon- α and interleukin-2 is the treatment of choice for nonresectable or metastatic RCCs in humans, with up to 50% of patients exhibiting a measurable response (Rathmell, Godley, and Rini, 2005). Anecdotally interferon- α (1.5 to 2 million units/m² subcutaneously three times per week) may have therapeutic effect in some dogs with RCC.

Sarcomas

Primary renal sarcomas are the rarest primary renal tumors in dogs and cats in published case series, accounting for 4% to 11% of all nonlymphoma primary renal tumors (Henry et al., 1999; Klein et al., 1988). However, in the NCSU Oncology Service referral population 24% of primary renal tumors in dogs were hemangiosarcomas. Other reported renal sarcomas include fibrosarcoma, osteosarcoma, and anaplastic sarcoma. Clinical signs of renal sarcomas other than hemangiosarcoma are usually identical to those seen with RCC, and treatment and typical disease progression appear to be similar. Primary renal hemangiosarcoma may be less aggressive than visceral hemangiosarcoma arising from other sites, including slower rate of progression and decreased frequency of macroscopic metastasis at the time of diagnosis (Locke and Barber, 2006). Mean survival of 14 dogs was 278 days, with the worst outcome associated with hemoperitoneum at the time of diagnosis. Chemotherapy protocols for renal hemangiosarcoma have not been evaluated thoroughly, although a doxorubicin-based protocol likely is appropriate (see Chapters 65 and 66). Insufficient cases exist to reliably predict behavior or prognosis of other renal sarcomas, although a combination of surgery and adjuvant chemotherapy is recommended.

Nephroblastomas

Nephroblastomas are renal tumors that are thought to arise from undifferentiated embryonic elements (blastema). Diagnosis requires the presence of epithelial, stromal, and blastema elements within the tumor (Khouri, 2005). These tumors are histologically diverse and often may be confused with RCCs or sarcomas

because of the predominance of one cell type. In humans nephroblastomas are also called Wilms' tumor and occur at much higher frequency in children (Khoury, 2005). Specific chromosomal mutations have been noted in many humans, but nephroblastomas in dogs and cats have not been examined yet for similar genetic alterations. Veterinary patients with nephroblastoma are often younger than patients with other primary renal tumors. Although dogs and cats as young as 1 year of age have been reported, clinical experience and published cases suggest that a second peak of occurrence exists at approximately the same age as other primary renal tumors. Hematuria is reported more frequently in patients with nephroblastoma than with other primary renal tumors. It appears that nephroblastomas are less likely to metastasize than other primary renal tumors and have a much better long-term prognosis; nephrectomy may be curative, although adjunctive chemotherapy should be given in cases in which histology suggests a less differentiated, more aggressive tumor. When metastasis does occur, the spinal cord is a common site.

Multifocal Renal Cystadenocarcinoma and Nodular Dermatofibrosis

Several related families of German shepherd dogs and German shepherd crossbreeds develop a syndrome of bilateral multifocal renal cystadenocarcinomas, nodular dermatofibrosis, and uterine leiomyomas; this disease also occurs sporadically in non-German shepherd dogs. Evidence suggests that affected dogs may have mutation in one allele of folliculin, a protein of unknown function; homozygous mutants are thought to die in utero. Histopathologic changes are similar to those noted in vitro with transforming growth factor- β dysregulation. Multiple renal cysts can be detected by imaging studies as early as 4 to 5 years of age, although diagnosis usually does not occur until later. Owners most commonly present their dogs for evaluation of diffuse skin nodules between 3 and 12 years of age (mean 8 years) (Moe and Lium, 1997). Renomegaly can be palpated in most dogs at the time of presentation. Long-term prognosis is poor since metastasis and renal failure are common; mean age at death is 9 years (Moe and Lium, 1997). Nephrectomy is contraindicated because both kidneys invariably are affected. Chemotherapy may be attempted, but successful therapy has not been reported; drugs that theoretically may be useful include paclitaxel and pirfenidone, although neither has been evaluated in clinical cases.

Lymphoma

Renal lymphoma is the most common kidney tumor in cats. At the NCSU Oncology Service 91% of renal tumors in this species were diagnosed as isolated or primary renal lymphoma. Unlike patients with other primary renal tumors, cats with renal lymphoma do present with signs and clinicopathologic changes of acute renal failure; up to 80% of cats have increased serum creatinine concentrations at the time of diagnosis (Mooney et al.,

1987). On physical examination the kidneys are usually bilaterally enlarged and irregular and may be painful when palpated. Renal shape and size are very similar to those in cats with severe polycystic kidney disease; abdominal ultrasound can be used for differentiation of the two diseases. The urinalysis is usually unremarkable with the exception of decreased urine concentration. Feline leukemia virus (FeLV) is strongly associated with development of renal lymphoma—approximately 50% of affected cats are FeLV positive (Mooney et al., 1987). Central nervous system involvement occurs at an increased frequency in cats with renal lymphoma, with approximately one third of cats developing neurologic abnormalities; most cats first exhibit signs of central nervous system involvement after disease recurrence rather than at the time of initial diagnosis (Mooney et al., 1987). Renal lymphoma is considered as advanced disease in most staging schemes; some oncologists classify affected cats as having stage III lymphoma, whereas others describe lymphoma in cats solely based on anatomic site.

Chemotherapy protocols for cats with renal lymphoma typically are the same as those for lymphoma affecting other parenchymal organs, usually incorporating L-asparaginase, vincristine, doxorubicin, cyclophosphamide, and prednisone (see Chapters 65 and 73). Approximately 60% of cats achieve complete remission, with a mean duration of remission of 372 days (median 127 days) and mean survival of 408 days (median 169 days) (Mooney et al., 1987). Nephrectomy is not recommended because, even though disease may not be overtly bilateral, both kidneys invariably are affected. Negative prognostic indicators include involvement of other organ systems (particularly the central nervous system), FeLV infection, and severity of renal failure, although larger studies are still needed to determine the relative weight of these factors (Mooney et al., 1987). Azotemia often improves dramatically with treatment of lymphoma so that renal failure is the eventual cause of death in a minority of cases. However, residual renal damage does persist in most cases and may affect ongoing decisions regarding treatment.

Dogs with stage V lymphoma may have neoplastic infiltration of the kidneys, particularly once disease has progressed to the terminal stages. As with cats, primary renal lymphoma cases do occur, although less frequently than carcinomas, sarcomas, or nephroblastomas. Dogs with renal lymphoma are less likely than cats to present with signs of uremia. Affected patients are more likely to show nonspecific signs of illness, with renal masses diagnosed on subsequent physical examination or diagnostic imaging studies. Both unilateral and bilateral renal involvement may occur; affected kidneys may be diffusely infiltrated or have masslike lesions. Dogs with primary renal lymphoma typically have limited involvement of other organs. As with cats, chemotherapy is the primary treatment for primary renal lymphoma in dogs. Protocols are the same as for dogs with nonrenal lymphoma (see Chapters 65 and 72), although dose modifications or alternate drug choices should be considered for renally excreted or nephrotoxic drugs. Unlike in cats, nephrectomy is a potential treatment option for dogs

with unilateral renal lymphoma. However, nephrectomy should be considered only if azotemia and decreased urine concentrating ability are absent, if abdominal ultrasound or contrast radiography suggests only unilateral disease, and if no other sites of disease are identified. Adjunctive chemotherapy is recommended following nephrectomy.

Transitional Cell Carcinomas

Transitional cell carcinomas (TCCs) arise from the renal pelvis and make up approximately 20% to 30% of primary renal neoplasms in dogs and cats (Henry et al., 1999; Klein et al., 1988). Although not considered to be of renal origin, these tumors usually invade the renal parenchyma and have the same clinical course and treatment options as RCC and primary renal sarcomas. Compared to those tumors, TCCs are more likely to cause urinary obstruction, hydronephrosis, and hematuria. Differentiation of TCCs from high-grade/undifferentiated RCCs may be difficult; on careful review tumors in both groups are often reclassified (Henry et al., 1999).

Metastasis of Extrarenal Neoplasms

Because renal blood flow makes up approximately 15% of total cardiovascular output, metastasis of neoplastic cells to the kidney often occurs. Microscopic or gross infiltration by tumor cells is a common postmortem finding in animals that have died of metastatic neoplasia. Of the three tumor subtypes (carcinoma, sarcoma, and round cell tumors), carcinomas are most often implicated in metastatic spread of cancer to the kidneys. Interestingly, azotemia or clinical signs of renal failure are rare even when a large proportion of renal parenchyma has been infiltrated. Nonspecific treatment of renal failure (e.g., change to a renal-formulated diet, phosphate binders) should be instituted when necessary. Standard chemotherapy protocols should be altered to minimize administration of nephrotoxic agents if concurrent renal disease is suspected or confirmed.

Benign Tumors

Benign tumors account for 5% to 17% of primary renal tumors in dogs and cats (Henry et al., 1999; Klein et al., 1988). Adenomas, transitional cell papillomas, fibromas, mesoblastic nephromas, and hemangiomas have been reported. These tumors are most commonly incidental postmortem findings, although occasionally they may cause microscopic or gross hematuria or urinary obstruction. If diagnosed antemortem, vigilant monitoring or partial nephrectomy should be considered since insufficient cases have been described to exclude the possibility of malignant transformation.

Other Considerations

Paraneoplastic Syndromes

Primary renal tumors are rarely associated with paraneoplastic syndromes. Published case series of renal tumors in dogs and cats report an apparent incidence of less than 5% (Henry et al., 1999; Klein et al., 1988). Polycythemia

secondary to excess production of erythropoietin is the most common paraneoplastic syndrome caused by renal neoplasia. Although not a true paraneoplastic syndrome, polycythemia may also occur when renal tumors decrease local oxygen concentration, resulting in excess erythropoietin production by nonneoplastic renal epithelial cells. Polycythemia may be an incidental finding noted on complete blood count, or animals may present with epistaxis or central neurologic abnormalities such as disorientation or seizures. Measurement of serum erythropoietin concentration is of questionable value; erythrocytosis and presence of a renal mass usually are sufficient for diagnosis. Renal tumors reported to cause polycythemia in dogs include renal carcinomas, fibrosarcoma, and lymphoma; renal carcinoma has been associated with polycythemia in a cat. Nephrectomy typically results in resolution of the polycythemia, although metastasis of functional neoplastic cells may prevent resolution.

Other paraneoplastic syndromes reported in dogs with renal tumors include extreme leukocytosis, hypertrophic osteopathy, and hepatopathy. Paraneoplastic leukocytosis is caused by excess production of granulocyte-macrophage colony-stimulating factor. The profound leukocytosis is the result of a mature neutrophilia (although low numbers of immature cells are occasionally seen), with as many as 200,000 neutrophils/ μ l blood reported. This extreme neutrophilia usually does not result in any clinical signs, although mild hypoglycemia may occur. Hypertrophic osteopathy usually is palpable as firm swelling of the distal long bones, most prominent in the metaphyseal regions, and can be very painful. These two syndromes may occur concurrently, and both may resolve following successful tumor resection. Mild hepatopathy, characterized by elevations in alkaline phosphatase and γ -glutamyltransferase without concurrent hyperbilirubinemia, is common in humans with renal tumors; this syndrome has been reported in a dog with a sarcomatoid RCC.

Complications of Extra-Renal Cancer on the Kidney

Azotemia is common in dogs and cats with paraneoplastic hypercalcemia. A variety of tumor types may secrete parathyroid hormone-related protein (PTHrp) or other humoral factors that increase calcium release from bones and promote calcium absorption from the gastrointestinal tract (see Chapter 54). Although PTHrp is thought to exert its function by the same mechanisms as PTH, dogs and cats with hypercalcemia of malignancy usually have higher serum calcium and phosphorus concentrations and are more likely to develop kidney disease than those with hyperparathyroidism. Kidney damage may occur through a combination of mineralization of tubular basement membranes, dysregulated renal tubular cell mitochondrial function, dehydration secondary to hypercalcemia-induced polyuria, and alterations to glomerular filtration rate. Therapy for patients with hypercalcemia and kidney disease should include diuresis with 0.9% sodium chloride. Loop diuretics (e.g., furosemide) may be used to increase renal calcium excretion but should not be used before rehydration, and patients should be maintained on intravenous fluid therapy during administration. Bisphosphonate drugs inhibit osteoclast function and reduce mobilization of calcium stores

from bones. Pamidronate is highly effective when given at a dose of 1 to 2 mg/kg intravenously diluted in 0.9% NaCl and administered over 4 hours; faster infusions may cause nephrotoxicity. Prednisone may also be used to promote calciuresis but should only be considered once lymphoma has been excluded definitively as the cause of hypercalcemia; glucocorticoids can mask disease, making diagnosis more difficult, and also may worsen long-term prognosis.

Kidney disease is found in a high proportion of humans with monoclonal gammopathies secondary to multiple myeloma or B-cell lymphoma. Contributing factors may include obstruction of renal tubules by light chains, toxicity to renal tubular epithelial cells via large-scale resorption and degradation of proteins, deposition of immunoglobulin light chains within the renal parenchyma, decreased renal perfusion caused by serum hyperviscosity, and tumor infiltration of the kidney. Obstruction of renal tubules and tubular cell toxicity (so-called *cast nephropathy*) has not been described definitively in dogs or cats. Immunoglobulin light chains also may cause amyloidosis or fibrillary nephropathy in humans, although only sporadic cases of light-chain-associated renal amyloidosis have been reported in dogs and cats. Syndromes of tubular cell dysfunction such as Fanconi syndrome or renal tubular acidosis have been reported in humans with multiple myeloma but have not been described in dogs or cats.

Glomerulonephritis in dogs and cats presumptively may occur secondary to any extrarenal inflammatory disease, including neoplasia. Membranous glomerulopathy is associated with carcinomas in humans in whom protein-losing nephropathies may develop while neoplasia remains occult. In dogs, although only approximately 30% of patients with glomerulonephritis are reported to have an identifiable concurrent extrarenal disease, the true incidence is likely much higher. Neoplasms reported to cause protein-losing nephropathies in dogs and cats include leiomyosarcoma, adrenal adenocarcinoma, and parathyroid adenoma (membranoproliferative glomerulonephritis); hemangiosarcoma, osteosarcoma, and mast cell tumor (membranous glomerulopathy); and mammary tumors and Sertoli cell tumor (reactive amyloidosis). TCC, bronchogenic adenocarcinoma, and lymphoma have also been reported to cause glomerulonephritis, although the histologic subtype was not described. Dogs with lymphoma or osteosarcoma may have microalbuminuria despite the absence of overt (positive standard urine dipstick) proteinuria.

Urinary obstruction secondary to neoplasms of the ureters, bladder, or urethra is a rare cause of postrenal azotemia and progressive renal injury. Surgical relief of obstruction is indicated, although azotemia in the presence of unilateral renal obstruction implies significant dysfunction of the contralateral kidney.

Tumor lysis syndrome, which occurs secondary to massive release of intracellular contents (particularly phosphorus, uric acid, and potassium) after chemotherapy in some dogs or cats with lymphoma, is another rare cause of renal failure. Precipitation of uric acid, calcium phosphate, or hypoxanthine in renal tubules, as well

as cytokine-induced perturbations in renal blood flow, leads to rapid renal failure and often death in humans. Treatment should include rehydration and maintenance of renal perfusion via isotonic crystalloids, alkalinization of urine to inhibit uric acid precipitation, and appropriate treatment of life-threatening hyperkalemia and hypocalcemia.

Effects of Chemotherapy on the Kidney

Several chemotherapy agents are either regularly associated with nephrotoxicity or have been reported to cause renal disease as idiosyncratic reactions (also see chapters 65 and 66). The platinum compounds (primarily cisplatin) cause acute tubular necrosis by accumulation of platinum within proximal convoluted tubular cells. Diuresis with 0.9% saline is recommended both before and following treatment with cisplatin. Recommended protocols vary, but the NCSU Oncology Service administers 0.9% saline at 18.3 ml/kg/hour intravenously for 4 hours, and then administers cisplatin at the same diuresis rate over 20 minutes, followed by 2 more hours of diuresis at the same rate. Pretreatment with mannitol has also been suggested but is no longer routinely used. Streptozotocin also causes tubular necrosis, and a similar diuresis protocol is recommended.

Doxorubicin causes renal disease in cats by unknown mechanisms. Clinicians should consider alternative agents or more aggressive diuresis in cats with preexisting renal disease, and doxorubicin should be stopped in cats that develop proteinuria or azotemia during therapy. Methotrexate has been reported to cause tubular necrosis in dogs, although this is uncommon. Lomustine (CCNU) may cause idiosyncratic acute renal failure, although this is also very rare.

Management of Feline Ureteroliths

ANDREW E. KYLES, *Davis, California*
JODI L. WESTROPP, *Davis, California*

URETEROLITHIASIS

Ureterolithiasis has emerged as an important cause of acute and chronic renal disease in cats over the last 15 years (Fig. 202-1). The emergence of ureterolithiasis has coincided with a dramatic change in the relative frequency of struvite and calcium oxalate (CaOx) uroliths in cats. In the 1970s and 1980s struvite urolithiasis predominated, but in 1993 CaOx superseded struvite as the most common urolith type and continues to be the most common mineral analyzed from cats at the Gerald V. Ling Urinary Stone Analysis Laboratory (Fig. 202-2). This change in urolith composition presumably is at least partially associated with dietary modification, such as urine acidification of proprietary cat food, to reduce the prevalence of struvite urolithiasis. Formation of CaOx uroliths does not depend on urine pH; however, highly acidifying diets can cause mobilization of calcium and phosphorus from the bone and therefore increase the concentration of these minerals in the urine. In a recent study we reported that 98% of feline ureteroliths contained CaOx (Kyles et al., 2005a). Therefore the emergence of ureterolithiasis may be associated with an increased prevalence of CaOx urolithiasis in cats, an increased awareness of ureterolithiasis, and/or an increased use of diagnostic imaging in cats with renal dysfunction.

The pathogenesis of CaOx urolithiasis in cats is poorly understood. Certain breeds such as Himalayan and

Persian have an increased risk ratio for CaOx urolithiasis (OR = 4.39 and 2.82, respectively). In humans approximately 75% of kidney stones are composed predominantly of CaOx, and oxalate metabolism is thought to play a crucial role in stone development. Hyperoxaluria can occur from increased dietary intake, as well as from a loss or diminished activity of oxalate-degrading bacteria in the colon (*Oxalobacater formigenes*). Humans are also much more prone to developing nephrolithiasis, particularly in industrialized nations. Although urinary supersaturation with crystals is implicated in stone formation in humans, several studies have investigated the possibility that the urine is not the initial site of stone development. A vascular etiology for nephrolithiasis in humans has been proposed, suggesting that vascular abnormalities (e.g., hypertensive vascular injury, atherosclerosis) can lead to Randall's plaques (papillary lesions that are usually associated with calcium and phosphate or CaOx deposition) (Stoller et al., 2004). It has been hypothesized that the initiating event in CaOx nephrolithiasis in humans may occur in the vascular bed at the tip of the renal papilla, a deviation from traditional concepts regarding urolith initiation (e.g., urinary stasis, infection). No studies investigating this hypothesis have been published in cats or dogs.

Other intraluminal causes of ureteral obstruction include soft-tissue plugs (which sometimes contain flakes of mineralized material), pyelonephritis debris, and calculi that appear to be composed of dried solidified blood

(DSB). These DSB calculi are very firm and “stonelike” but usually do not contain crystalline material (Westropp et al., 2006). The incidence of DSB calculi in cats also seems to be increasing (Fig. 202-3). These calculi are a particular diagnostic challenge because they are not visible on survey radiographs and are rarely identified during ultrasonographic examination.

SIGNALMENT

Ureterolithiasis tends to develop in middle-aged or older cats, with a median age at diagnosis of 7 years. Cats as young as 8 months have been diagnosed with ureteral calculi. There is no sex predilection.

CLINICAL SIGNS

Clinical signs are commonly nonspecific, including reduced appetite, weight loss, lethargy, and hiding. Cats

also may present with hematuria without concurrent lower urinary tract signs such as stranguria, pollakiuria, and dysuria. Often cats may present with variable signs of renal failure, including vomiting, polyuria and polydipsia, and anuria. Some obstructed cats with severe azotemia experience surprisingly few clinical signs, whereas a few present in a moribund, hypothermic state. Kidney size can be normal, increased, or decreased and is frequently asymmetric. Abdominal pain, which is commonly reported in humans with ureteral calculi, is rarely recognized in cats.

CLINICOPATHOLOGIC FINDINGS

There is marked variation in serum creatinine and blood urea nitrogen concentrations in cats with ureteroliths. Factors that affect the degree of azotemia include whether the ureteral calculi are unilateral or bilateral, the degree of ureteral obstruction, the degree of impairment of renal function in each kidney, and the severity of prerenal azotemia. Although cats with bilateral ureterolithiasis tend to have higher serum creatinine and blood urea nitrogen concentrations, 76% of cats with unilateral ureteral calculi are azotemic, indicating impairment of renal function in the contralateral kidney, obstruction of the contralateral ureter, or prerenal azotemia (Kyles et al., 2005a).

DIAGNOSTIC IMAGING

Diagnostic imaging of the abdomen should be performed in all cats with acute or chronic renal failure. With the exception of most DSB calculi, all the ureteral calculi we have analyzed contain CaOx or calcium phosphate and therefore are radiopaque. The sensitivity of survey abdominal radiography for the diagnosis of ureterolithiasis is 81% (Kyles et al., 2005a). Small calculi, calculi overlying the colonic contents, and radiolucent calculi may be missed on survey radiographs. Ureteral calculi are most readily identified in the retroperitoneal area on the lateral radiographic projection; however, visibility on lateral radiographs alone can lead to difficulty in determining which ureter is involved or whether one or both ureters are affected.

The sensitivity of abdominal ultrasonography for the diagnosis of ureteral calculi is 77% (Kyles et al., 2005a). Partial or complete ureteral obstruction, indicated by dilation of the renal pelvis, ureter, or both, is observed in 92% of cats. Ureteral dilation tends to begin proximally and, as the degree of hydroureter increases, extend distally. The hydroureter often does not extend to the level of the ureteral calculus; this may explain why the calculus is not identified in 23% of cases. A combination of survey radiography and ultrasonography is recommended and has a sensitivity of 90% for the diagnosis of ureterolithiasis.

Additional imaging modalities such as antegrade pyelography or computed tomography (CT) may be necessary to identify calculi that are not apparent on survey radiographs or ultrasonography. Percutaneous antegrade pyelography can be used to determine if ureteral obstruction is present. A 2.5-inch, 25-gauge spinal needle is placed through the parenchyma of the kidney into the renal pelvis under ultrasound guidance. Urine is withdrawn, which can be submitted for cytologic examination and bacteriologic culture. A volume of aqueous, iodinated contrast media equal to half the volume of urine removed is infused into the pelvis. Care should be taken not to inadvertently advance the needle through the renal pelvis into the abdomen because this can result in uroabdomen. Contrast-enhanced CT is superior to other imaging modalities for determining the presence of ureteroliths, their number, and position. In our practice CT has largely replaced antegrade pyelography for imaging cats with apparent ureteral obstruction if ureteral calculi cannot be identified by survey radiographs and ultrasound.

Intravenous urography and nuclear scintigraphy are of limited use because ureteral obstruction reduces the filtration of contrast media or isotope. This results in poor opacification of the upper portion of the urinary tract during intravenous urographic studies and an artificial decrease in the calculated glomerular filtration rate (GFR) with nuclear scintigraphy. Scintigraphic measurement of individual kidney GFR may aid in prognosis and management decisions, particularly if nephrectomy of the obstructed kidney is considered.

MEDICAL MANAGEMENT

All cats with ureteral calculi receive medical management until it is determined whether the ureteral calculi will pass into the bladder. Conservative medical management for stable cats generally consists of supportive therapy for renal failure (Chapters 190 and 191) and treatments designed to increase the likelihood of relief of ureteral obstruction. Fluid diuresis alone or in combination with diuretic drug therapy (furosemide, mannitol) may improve the likelihood of passage of ureteral calculi. In humans intravenously administered glucagon causes relaxation of the ureteral smooth muscle and promotes passage of calculi. In cats we did not observe any beneficial effects of glucagon (0.1 mg per cat intravenously). Other drugs such as α -adrenergic antagonists (prazosin, tamsulosin), amitriptyline (a tricyclic antidepressant), and calcium channel blockers have also been used to facilitate ureterolith passage in humans; but there are no reported studies of the use of these drugs in cats with ureterolithiasis.

Cats with markedly high serum creatinine concentrations at the time of initial examination benefit from aggressive medical management such as hemodialysis or emergency nephrostomy catheter placement, although the mortality rate in cats undergoing these treatments is significantly higher than in cats that do not undergo them (Kyles et al. 2005b). The aim of dialysis or emergency nephrostomy catheter placement is to reduce the degree of azotemia, allow time to determine whether the calculus will pass on its own, and improve the clinical condition of the cat in preparation for surgery. Seventy-two percent (13 of 18) of cats treated with dialysis survived to surgery, three cats died, and two experienced a marked reduction in the degree of azotemia without surgery, presumably because of passage of the ureterolith (Kyles et al., 2005b). Nephrostomy catheters can be placed either via an emergency laparotomy or by an ultrasound-guided, percutaneous technique. By alleviating the postrenal component of azotemia, preoperative nephrostomy catheter placement has the added advantage of allowing a preoperative assessment of the remaining renal function in the obstructed kidney.

During conservative management cats are monitored by serial measurement of serum creatinine and blood urea nitrogen concentrations and serial ultrasonography or abdominal radiography. Repeated imaging studies should be performed in cats undergoing medical therapy to document passage of calculi. The degree of improvement in renal function after passage of the ureteral calculus is variable, with some cats experiencing a marked decrease in azotemia and others showing little or no change in the serum creatinine concentration, presumably reflecting the underlying degree of irreversible renal dysfunction. In cats treated medically that survived longer than 1 month after diagnosis, the 12-month survival rate was 66%, with a number of cats dying of causes related to chronic renal insufficiency or recurrent ureterolithiasis (Kyles et al., 2005b). Fifty percent of cats (6 of 12) had a serum creatinine concentration greater than the upper reference limit at 6 to 12 months after diagnosis (Kyles et al. 2005b).

SURGICAL MANAGEMENT

Surgical removal of ureteral calculi is warranted when there is evidence of partial or complete ureteral obstruction, as indicated by hydronephrosis and dilation of the ureter proximal to the obstruction, and when the calculus is immobile on repeated imaging examinations. Major factors determining the recovery of renal function after reestablishing ureteral patency include the duration and extent of the obstruction. In research dogs GFR is almost completely recovered after relief of complete ureteral obstruction within 4 days, 46% of GFR returned after 14 days of obstruction, and almost no GFR returned after 40 days of obstruction. In cats the optimal time for medical management before making a decision to pursue surgery has not been determined. The reported median interval between diagnosis and surgery was 3 days (Kyles et al., 2005b).

The surgical technique used depends on the location of the calculus and the preference of the surgeon. The two most common techniques for removing ureteral calculi are

ureterotomy and *partial ureterectomy combined with ureteroneocystostomy*. For both techniques surgical magnification is required, and use of an operating microscope preferred.

Ureterotomy

Ureterotomy is indicated in cats for the removal of intraluminal ureteral obstructions and can be performed at any level of the ureter. If the ureteral calculus cannot be readily identified, a piece of suture material can be advanced up the ureter from the bladder to identify the level of the obstruction. The ureter should be handled with care, and the blood supply preserved. The ureter is surrounded by fat, which should be dissected away from the ureter. A longitudinal incision is made with a scalpel blade and extended with scissors. Normally the calculus is readily removed, although occasionally it becomes embedded in the ureteral wall. Care should be taken to prevent a ureteral calculus from inadvertently being pushed back into the renal pelvis. After calculus removal the ureter is flushed with sterile saline, and a catheter or length of suture material is passed proximally into the renal pelvis and distally to the level of the bladder to ensure that the ureter is patent. The ureterotomy is closed with 8-0 monofilament suture material. A simple continuous suture pattern is preferred. The most common complication in cats is urine leakage and uroabdomen, which is reported in 16% of cats after ureterotomy (Kyles et al., 2005b).

Partial Ureterectomy and Ureteroneocystostomy

Ureteroneocystostomy involves reimplantation of the distal ureter into the bladder and is used to reestablish urine flow after resection of the distal ureter. The technique is most often performed to remove distal ureteral calculi, although up to 80% of the feline ureter can be resected, and ureteroneocystostomy successfully achieved if appropriate tension-relieving techniques are applied. Techniques for ureteroneocystostomy can be divided into intravesicular (e.g., the mucosal apposition technique), which are performed from within the bladder and require a cystotomy for access, and intravesicular (e.g., the modified Lich-Gregoir technique). The modified Lich-Gregoir technique is preferred in cats, particularly cats with minimum preexisting ureteral dilation, because it is associated with a reduced degree of postoperative swelling and ureteral obstruction (Mehl et al., 2005).

For the modified Lich-Gregoir technique, a 1-cm seromuscular incision is made at the apex of the bladder, and a 0.5-cm incision is made in the mucosa at the caudal aspect of the seromuscular incision. The distal 0.5- to 1-cm of the ureter is dissected free from the periureteral fat and spatulated. The mucosa of the ureter is sutured to the bladder mucosa using a simple interrupted pattern and 8-0 monofilament suture material. The first suture is placed at the apex of the spatulation, and the second at the distal end of the spatulation. A length of 5-0 suture material is placed into the ureter to ensure patency. A minimum number of mucosal sutures, usually six, is required because an excessive number of sutures increase the risk of postoperative ureteral obstruction. The seromuscular layer is closed using a simple interrupted pattern

and 5-0 monofilament suture material. The mucosal layer should provide accurate mucosal apposition, whereas the seromuscular layer provides the watertight seal. Uroabdomen is the most common complication of ureteroneocystostomy and occurs with a similar frequency to that observed after ureterotomy in cats with ureteral calculi (15%) (Kyles et al., 2005b). Cats should be evaluated carefully for postoperative ureteral obstruction at the level of the stoma after ureteroneocystostomy. Routine monitoring of serum creatinine concentrations with serial ultrasound examinations is indicated in the postoperative period.

Ureteroureterostomy

Ureteroureterostomy is performed rarely in cats with intraluminal obstructions. The technique is technically more difficult than ureteroneocystostomy and can be recommended only when a portion of the proximal ureter is resected and the ureter cannot be reimplanted into the bladder. The chances of ureteral stricture are reduced by increasing the circumference of the anastomosis by spatulation. It is also possible to attach the ureter to the contralateral ureter (transureteroureterostomy).

Techniques for Tension Reduction

Tension on the ureteroneocystostomy or ureteroureterostomy anastomosis increases the risk of dehiscence or stricture formation and should be avoided. Tension can be reduced by *renal descensus* and *psoas cystopexy*. Renal descensus involves dissecting the kidney from its retroperitoneal attachments and performing a nephropexy to attach the kidney to the body wall in a more caudal location. Psoas cystopexy involves pulling the apex of the bladder craniolaterally toward the kidney and suturing the bladder to the psoas muscle dorsally. It is also possible to dissect the kidney from its retroperitoneal attachments and suture the kidney directly to the bladder (nephrocystopexy) if necessary.

Nephrostomy Catheters

The feline ureter is too small to allow placement of a ureteral stent. Nephrostomy tubes have been recommended for urine diversion following ureterotomy in cats. However, complications related to nephrostomy catheter placement are common and include uroabdomen, poor drainage, and catheter dislodgment. In cats with ureteral calculi a ureterotomy can be performed without placement of a nephrostomy catheter (Kyles et al., 2005b).

Nephrotomy

Nephroliths are common in cats with ureteral calculi. One study reported radiographic or ultrasonographic evidence of nephroliths in 62% of cats with ureterolithiasis (Kyles et al., 2005a), although this is probably an overestimation since it can be difficult to differentiate renal calculi from renal pelvic calcification. In most of these cats a nephrotomy is not indicated based on traditional criteria such as obstruction of urine flow, pain, or chronic pyelonephritis. However, there is justifiable concern that a nephrolith

may move into the ureter and cause another episode of ureteral obstruction. The counter argument is that a cat with a degree of ureteral obstruction may be more likely to leak urine through a concurrent nephrotomy incision. We have not routinely performed a nephrotomy in cats with concurrent ureteral and renal calculi. One interesting approach is to perform a mini-nephrotomy approach to allow insertion of an endoscope and endoscopic retrieval of calculi in the renal pelvis or proximal ureter (Kuntz, 2005). Unfortunately recurrence of urolithiasis and ureteral obstruction is possible regardless of whether or not nephroliths are removed.

Nephrectomy

Nephrectomy can be considered in cats with unilateral ureteral obstruction and adequate function in the contralateral kidney. However, ureteral obstruction may be bilateral, and renal function is often already compromised in both kidneys in affected cats, precluding sacrifice of one kidney. Furthermore, there is a risk of recurrence of obstruction in the contralateral kidney. For these reasons definitive surgery rather than nephrectomy is usually indicated.

Renal Transplantation

Renal transplantation is a viable treatment for chronic kidney disease in cats after relief of the ureteral obstruction. There is a risk of formation of calculi in the allograft. In transplant patients with a history of urolithiasis, it is recommended to use absorbable suture material in the urinary tract, to carefully monitor for urinary tract infection, and to feed a diet designed to prevent the recurrence of CaOx calculi. In one group of cats there was no difference in the long-term outcome for allograft recipients when stone formers were compared to cats with an underlying cause of renal failure that was not related to urolithiasis (Aronson et al., 2006).

Prognosis for Surgical Treatment

The overall morbidity and mortality rates for the postoperative period, defined as the first month after surgery, are 31% and 18%, respectively (Kyles et al., 2005b). In cats that survived longer than 1 month after surgery, the 12-month survival rate was 91%, with a number of cats dying of causes related to chronic renal insufficiency, recurrent ureterolithiasis, or nonregenerative anemia (Kyles et al. 2005b). Fifty-two percent of cats (23 of 44) had a serum creatinine concentration greater than the upper reference limit at 6 to 12 months after diagnosis (Kyles et al. 2005b).

RECURRENCE

Because of the possibility of recurrence of CaOx uroliths, several proposed management strategies should be implemented. If serum calcium concentration is elevated, a search should be initiated for underlying causes such as primary hyperparathyroidism, neoplastic processes, renal secondary hyperparathyroidism, and idiopathic hypercalcemia in cats (Chapter 52). Appropriate medical and dietary management should be instigated in cats with renal failure. Hypocitraturia is a risk factor for CaOx

Box 202-1

Commercial Diets Marketed To Assist With Prevention of the Formation of CaOx Calculi in Cats

- Eukanuba Veterinary Diets Nutritional Urinary Formula Moderate pH/O/Feline canned and dry
- Hill's Prescription Diet Feline x/d canned and dry
- IVD Feline Mature Formula canned and dry
- IVD Feline Modified Formula canned and dry
- Purina Veterinary Diets NF Kidney Function Feline Formula canned and dry
- Royal Canin Veterinary Diet Feline Urinary SO canned and dry

stone formation in humans because citrate is chelated to calcium, forming a more soluble salt. Citrate supplementation appears beneficial in humans, but no studies are available in cats that evaluate the effect of citrate supplementation on CaOx calculus formation. If supplementing potassium citrate (75 mg/kg orally BID), the serum potassium concentration should be evaluated periodically, particularly if renal function is compromised, to be certain the cat does not become hyperkalemic. Potassium citrate is also reported to interact with aluminum-containing phosphate binders. Hydrochlorothiazide is a diuretic that decreases urine calcium excretion in humans and has been recommended to prevent recurrence of CaOx formation in dogs. Again, studies in affected cats are lacking.

Many diets are marketed to prevent the recurrence of CaOx uroliths in cats with normal renal function (Box 202-1). The cat should never be offered the new diet while hospitalized, and the new diet should be placed next to the old one so the cat can transition to the preferred diet slowly. Periodic urine samples should be evaluated. The urine should be relatively dilute (<1.025), and the sediment should be free of pronounced crystalluria. Serial abdominal imaging studies should be performed to detect recurrence of CaOx urolithiasis. Further information on CaOx urolith prevention can be found at: <http://www.vetmed.ucdavis.edu/vme/stonelab>.

Incomplete Urolith Removal: Prevention, Detection, and Correction

JODY P. LULICH, *St. Paul, Minnesota*
CARL A. OSBORNE, *St. Paul, Minnesota*

Recurrence of uroliths following surgery is commonly attributed to failure of medical therapy to adequately reduce factors promoting urolith formation. However, this hypothesis is based on the premise that all stones were completely removed from the urinary tract before therapeutic intervention. We performed a retrospective study of cystotomies performed to remove urocystoliths from 37 dogs and 29 cats in our veterinary teaching hospital. Incomplete removal of uroliths was documented in eight dogs and four cats. The observation that uroliths were detected in the lower urinary tract following cystotomy in 20% of cats and 14% of dogs in a teaching hospital with board-certified surgeons on the staff emphasizes an inherent risk associated with this procedure. Based on our experience and consultations with our colleagues in private practice, incomplete removal of uroliths occurs more frequently than is recognized. Remaining uroliths are commonly discovered several weeks or months following surgery when patients are reevaluated because of persistent or recurrent signs of lower urinary tract disease. In this situation delayed detection of uroliths often is erroneously attributed to recurrence (or rather pseudorecurrence). This in turn may result in inaccurate and inappropriate prognostic and therapeutic recommendations to prevent future recurrence. The most common cause of rapid recurrence of uroliths is incomplete surgical removal.

Pseudorecurrence can also occur when uroliths are eradicated by other modalities (e.g., medical dissolution, voiding urohydropropulsion, laparoscopic-assisted cystotomy, lithotripsy). The following discussion describes techniques to prevent, detect, and correct pseudorecurrence following surgical removal of uroliths. In most instances these principles and procedures can be applied to other methods of urolith eradication as well.

PREVENTING PSEUDORECURRENCE

Avoiding incomplete urolith removal requires a high degree of suspicion that, even when using best surgical techniques, considers that uroliths can evade detection and removal. To minimize this complication, the following procedures should be considered.

Inform the Client

When discussing the option of surgery to remove uroliths from the lower urinary tract, clients should be informed that even in the hands of experienced surgeons there is a risk that not all of the uroliths will be removed. To minimize this complication, appropriate procedures to assess success will be performed following surgery. Clients should also be informed of the consequences of incomplete removal of uroliths and the benefits and risks of therapeutic strategies available to manage this complication.

Confirm Urolith Location and Number Before Removal

Uroliths often migrate to lower portions of the urinary tract. Therefore, if several days have elapsed between the date of diagnostic imaging and the date of surgery scheduled to remove uroliths, the number and location of stones should be reevaluated by appropriate imaging methods just before surgery. This number can be compared with the number of stones removed. Disparities should arouse sufficient concern to pursue diagnostic procedures to rule out pseudorecurrence.

Reposition Urethroliths to the Urinary Bladder

To avoid performing two surgical incisions, urethroliths should be flushed into the urinary bladder before surgery. Retrograde urohydropropulsion is a simple and effective method of dislodging and propelling urethral stones into the urinary bladder. Following general anesthesia and just before surgery, approximately 30 ml of sterile lactated Ringer's solution or normal saline should be rapidly and forcefully flushed through the urethra using a flexible wide-bore catheter. It is important to remember to remove most of the urine from the urinary bladder (by decompressive cystocentesis or manual expression) before hydropropulsion to permit maximal retrograde hydrostatic pressure and to avoid iatrogenic bladder rupture caused by overfilling.

Consider Presurgical Urethral Catheterization

Placement of large-diameter catheters following retrograde urohydropropulsion has both benefits and risks.

Urethral catheterization can minimize the migration of urocystoliths back into the urethra. Placement of a cuffed (Foley) catheter such that the inflated balloon obstructs the trigone may more effectively prevent urolith migration than catheters without dilation capabilities. However, urethral catheterization increases the risk of iatrogenic infection. In addition, stones that enter the urethra with the catheter in place may become more securely wedged in the urethra as the catheter is withdrawn.

Strive for Complete Urolith Removal

Appropriate care should be taken to remove all uroliths from the bladder lumen, bladder neck, and urethra. Uroliths may be removed with the aid of spoons, forceps, gauze sponges, or suction devices. The lumen of the bladder and bladder neck should be explored with a finger to detect remaining uroliths. In addition, the bladder lumen should be flushed with an isotonic solution to remove subvisual uroliths.

Flush the Urethra Before Closing the Urinary Bladder

Uroliths that have passed into the urethral lumen during cystotomy are easily flushed back into the bladder lumen by injecting appropriate quantities of physiologic saline through a catheter placed in the external urethral orifice. It is important that the catheter tip reside only in the most distal portion of the urethra. The external urethral orifice should be occluded around the catheter to facilitate flushing of the urethroliths back into the bladder lumen. If the distal urethra is not occluded, fluid may flow around small urethroliths without moving them into the bladder. Appropriate caution must be used to minimize retrograde flushing of bacteria that normally colonize the mucosa of the distal urethra and genital tract into the urinary bladder and surgical site.

Normograde urethral flushing (i.e., inserting a flexible catheter in the urethral lumen via the urinary bladder) may also enhance patency of the urethra by forcing small uroliths out the distal urethral orifice. However, caution must be considered when flushing larger stones unable to exit the external urethral orifice. If attempted, some uroliths may become securely lodged in the urethra lumen such that their placement is not easily reversed by retrograde urohydropulsion.

DETECTING PSEUDORECURRENCE

Procedures that facilitate immediate detection of uroliths inadvertently left in the urinary tract following surgery have become a standard of practice. If uroliths obstruct the urethra before the cystotomy incision heals, life-threatening complications may develop. Also, if uroliths remaining in the lower urinary tract following surgery are first detected by radiography or ultrasonography several weeks after surgery, it may be assumed erroneously that the patient is highly predisposed to recurrent urolithiasis. The following options should be considered to accurately detect pseudorecurrence.

Urolith Number

When possible, the number of uroliths removed from the lower urinary tract should be compared with the number of uroliths detected by radiography, ultrasonography, or via cystoscopy. Incongruities in the count should raise suspicion that uroliths remain in the lower urinary tract, are deposited in the abdomen, or have been evacuated by suction.

Transurethral Catheterization

Normograde and retrograde passage of urinary catheters is a common method of assessing complete urolith removal. However, it is our opinion that it is an insensitive tool. This is especially true for uroliths with an irregular contour (e.g., calcium oxalate and silica) that allow catheters and flushing solutions to slide past when lodged in the urethral lumen.

Therefore large-bore catheters should be selected. Any resistance to advancement of the catheter through the urethral lumen should prompt appropriate evaluation of the urethra for persistent uroliths. Under these conditions forceful attempts to advance the catheter through the urethral lumen may inadvertently tear the wall of the urethra or cause the uroliths to become so firmly lodged in the urethral lumen that retrograde urohydropulsion is ineffective.

Radiography

Radiography is a valuable technique in the diagnosis of pseudorecurrence and has become the standard of care. In a recent case review by the Professional Liability Insurance Trust (PLIT) for the American Veterinary Medical Association, a veterinarian who does not perform radiography to verify complete removal of uroliths following cystotomy is practicing substandard care (PLIT, 2005). Therefore we recommend that appropriate medical imaging be performed following cystotomy to verify complete urolith removal.

Radiographic detection of residual uroliths depends on their size, location, and mineral composition. Although survey radiography is suitable for identification of radiopaque uroliths greater than approximately 2 to 3 mm in diameter, contrast-enhanced procedures are needed to identify uroliths composed of compounds similar to the radiographic density of soft tissue (e.g., ammonium urate, cystine, xanthine). Double-contrast cystography is the preferred technique because it has been associated with the highest sensitivity and lowest false-negative detection rates (Fig. 203-1). Although we commonly inject room air as the negative contrast agent, carbon dioxide (CO₂ refills and dispenser, Genuine Innovation) or nitrous oxide is preferred to minimize the risk of air embolization. Following instillation of negative contrast agent, we inject 1 to 4 ml of iodinated contrast, depending on bladder size. A minimum of three orthogonal views are recommended by some to completely evaluate the urinary bladder: left lateral, right lateral, and a ventrodorsal view. We routinely evaluate the urinary bladder with two lateral views, one before and one following bladder instillation of contrast

Fig. 203-1 Presurgical (**A**) and postsurgical (**B**) lateral survey radiographs of a 5-year-old male miniature Schnauzer illustrating multiple calcium oxalate uroliths in the bladder and urethra. Double contrast cystography (**C**) confirmed the number and location of pseudorecurrent uroliths.

agents. In some cases stones lodged in the pelvic urethra escape radiographic detection because they become obscured by the bones of the pelvis. If this is likely, rectal palpation of the pelvic urethra should be sufficient to detect their presence. Ultrasonographic examination is rarely useful immediately following surgery because additional air in the abdomen limits visualization. In addition, ultrasound examination does not detect residual stones located in the urethra.

Postsurgical Endouroscopy

For clinics with endoscopic capabilities, visually evaluating the lumen of the urinary tract is one of the most sensitive methods of detecting pseudorecurrence of urethroliths. Small-diameter flexible endoscopes are used in male dogs. Endouroscopy is of limited benefit in male cats because the narrow urethral lumen limits the availability of suitable equipment that can pass through the urethral lumen. Larger, rigid endoscopes are suitable for female dogs and cats. Endouroscopy not only has the advantage of identifying uroliths, but small stones capable of passing

through the urethra can be retrieved and removed (see sections on Basket Retrieval and Intracorporeal Lithotripsy later in the chapter).

CORRECTING PSEUDORECURRENCE

Depending on urolith size and shape, stones remaining after surgery may obstruct the urethra, contribute to hematuria, perpetuate urinary discomfort, and/or increase the risk of urinary tract infection. Therefore, to avoid these complications, uroliths should be removed promptly. Below are several therapeutic options for managing pseudorecurrent uroliths.

Spontaneous Voiding

Small uroliths capable of passing through the urethra may pass spontaneously, obviating the need for additional therapy. Following surgery normal bladder healing is associated with increased dysuria and pollakiuria, favoring increased bladder evacuation and subsequent urolith expulsion. It has been our experience that, if uroliths

have not voided spontaneously after 1 to 3 months, their spontaneous evacuation is unlikely to occur. After this time other methods of urolith removal should be considered.

Medical Dissolution

Pseudorecurrent uroliths composed of magnesium ammonium phosphate, cystine, or salts of urate can be dissolved medically. It is important to recognize that uroliths located in the urethra are not likely to dissolve because they are not surrounded by urine that is undersaturated for that particular mineral. Therefore urethroliths need to be flushed back into the urinary bladder, and their position periodically monitored to improve success of dissolution therapy.

Surgical Removal

Ideally patients should be evaluated for complete urolith removal immediately after completion of surgery and before recovery from anesthesia. This facilitates the surgeon's ability to reexplore the lower urinary tract without reanesthetizing the patient. If the patient's cardiovascular system is unstable, anesthesia should be discontinued, and the surgery postponed until potentially life-threatening complications can be controlled.

For some patients retrograde urohydropropulsion needs to be performed to flush urethroliths back into the urinary bladder. This should be performed before entering the surgical area. By doing so, the surgeon can better anticipate the approach to remove retained uroliths.

Basket Retrieval

Retrieving stones cystoscopically with a stone basket is ideal for removing small stones that can easily be pulled through the urethra. A variety of stone baskets are available to facilitate this technique (Stone Retrieval Grasping

Forceps, Boston Scientific; N-Circle Nitinol Tipless Stone Extractor, Cook Urologic, Inc.).

It is logical to ask, "Why can't they be removed by voiding urohydropropulsion?" Voiding urohydropropulsion is a simple and effective technique for urolith removal. However, excessive distention of the urinary bladder with saline and/or manual expression of the urinary bladder following surgery increases the chance of bladder rupture. Therefore voiding urohydropropulsion should be avoided.

Intracorporeal Lithotripsy

Intracorporeal lithotripsy is ideal for uroliths that become lodged in the urethra following surgery. In this situation the urethra often holds the urolith stationary, facilitating accurate and consistent delivery of laser energy. Under these conditions urethroliths are quickly fragmented into smaller pieces that can be retrieved or flushed out of the urinary tract. Lithotripsy can also be used to manage uroliths left in the bladder (see Chapter 204). Combined with basket retrieval techniques, lithotripsy is a safe and effective method of correcting pseudorecurrent uroliths.

Laser Lithotripsy for Uroliths

LARRY G. ADAMS, *West Lafayette, Indiana*

JODY P. LULICH, *St. Paul, Minnesota*

Lithotripsy is crushing or fragmenting uroliths by shock waves or laser energy. Types of lithotripsy include extracorporeal shock wave lithotripsy (SWL), electrohydraulic lithotripsy, and laser lithotripsy. SWL is mainly used for treatment of nephroliths and ureteroliths (Adams and Senior, 1999). Although electrohydraulic lithotripsy can be performed to fragment urocystoliths in larger female dogs (Adams and Senior, 1999), this technique has been replaced by the safer and more efficient laser lithotripsy method. Laser lithotripsy is a relatively new option for fragmentation and removal of lower tract uroliths visualized using rigid or flexible endoscopes (Adams and Lulich, 2006).

In humans laser lithotripsy using the holmium: YAG (Ho:YAG) laser has become the standard of care for intracorporeal fragmentation of uroliths. In humans laser lithotripsy is principally used for fragmentation of ureteroliths and small nephroliths (Lingeman, Lifshitz, and Evan, 2003). Although the Ho:YAG laser can be used to fragment and remove large staghorn nephroliths in humans, this approach is often not practical because the large stone burden requires prolonged or multiple procedures. Likewise, SWL has a lower success rate than percutaneous nephrolithotomy for removal of staghorn nephroliths (Lam et al., 1992). Therefore percutaneous nephrolithotomy is considered the procedure of choice for most large staghorn nephroliths (Lingeman, Lifshitz, and Evan, 2003).

Urolith size, number, and location are important considerations for selecting minimally invasive procedures (e.g., voiding urohydropulsion, laparoscopic-assisted cystotomy, and laser lithotripsy) for urolith management in dogs and cats (see also Chapter 203). Voiding urohydropulsion may be used to remove uroliths that are smaller than the diameter of the dilated urethra. Laser lithotripsy effectively extends the use of voiding urohydropulsion to larger uroliths by fragmenting uroliths into smaller pieces before transurethral evacuation (Figs. 204-1 and 204-2).

Prior in vitro studies confirmed that the Ho:YAG laser can efficiently fragment uroliths from dogs regardless of chemical composition (Wynn et al., 2003). Likewise, experimentally implanted urethroliths in male dogs were safely fragmented by laser lithotripsy using the Ho:YAG laser (Davidson et al., 2004). We recently reported successful laser lithotripsy fragmentation and removal of bladder and urethral calculi from dogs with spontaneously occurring uroliths (Adams and Lulich, 2006).

EQUIPMENT NEEDED FOR LASER LITHOTRIPSY

The Ho:YAG laser is the preferred laser for lithotripsy. The active medium of this laser is a crystal of yttrium, aluminum, and garnet (YAG) doped with holmium, with a wavelength of 2100 nm, which is in the near infrared portion of the electromagnetic spectrum. Because the 2100-nm wavelength of the Ho:YAG laser is absorbed in 0.5 mm of fluid, it can be used to safely fragment uroliths within the urethra or urinary bladder with minimal or no damage to the urothelium. The Ho:YAG laser energy is delivered in 350-microsecond pulses and is quickly dispersed in water surrounding the tip of the laser fiber. Ho:YAG lasers are available with total power ranging from 20 to 100 watts, but the lower-power lasers (20 to 30 watts) are adequate for laser lithotripsy.

Laser lithotripsy can be performed through small-diameter flexible ureteroscopes (e.g., 7.5 to 8.5 Fr), which are used for urethrocystoscopy in male dogs, and rigid cystoscopes (e.g., 9 to 19 Fr), which are used in female dogs and cats. The size of the cystoscope is based on the size of the dog or cat. The laser energy of the Ho:YAG laser is transferred from the laser unit to the surface of the stone through small-diameter (200- to 550-micron) flexible quartz laser fibers. These special fibers are passed through the working channel of the cystoscope. When working through the biopsy channel of rigid cystoscope, we use a 365- or 550-micron quartz laser. Both 200- and 365-micron fibers pass through the 3-Fr working channel of a flexible endoscope, although care must be used to avoid damaging the working channel with the rigid tip of the fiber. To protect the working channel from damage, a laser catheter can be passed through it before passage of the laser fiber. In the event of accidental discharge of the laser while the fiber tip is within the working channel of the scope, the laser catheter provides minimal protection to the scope. The smaller-diameter fibers have minimal impact on the ability to deflect the tip of flexible ureteroscopes and allow for efficient targeting of urethral calculi.

Additional equipment required for laser lithotripsy includes stone baskets used for extraction of urolith fragments. A variety of stone baskets are available from various manufacturers. We prefer tipless baskets that facilitate capture of small stone fragments within the urethra or bladder lumen. Although not essential, C-arm fluoroscopy is helpful to document urolith size and location during laser lithotripsy. This is most helpful in male dogs because

Fig. 204-1 Cystoscopic view of laser lithotripsy of a calcium oxalate urolith within the bladder lumen of a female dog. Note that the quartz laser fiber tip is in direct contact with the urolith surface. Small urolith debris can be seen as streaks within the saline used to distend the urinary bladder.

Fig. 204-2 Multiple urolith fragments in bladder lumen after laser lithotripsy fragmentation of the calcium oxalate urolith. The remaining urolith fragments are small enough to pass through the urethra.

of the limited visualization provided through flexible ureteroscopes. Fluoroscopy-aided retrograde contrast studies can also be performed to detect anatomic abnormalities associated with the uroliths and to document complete urolith removal. In female dogs and cats the entire bladder lumen can be readily visualized through the rigid cystoscope, making concurrent fluoroscopy less essential.

LASER LITHOTRIPSY TECHNIQUE

Laser lithotripsy is performed with urolith visualization by urethrocystoscopy. Detailed description of urethrocystoscopy is beyond the scope of this chapter and has been described elsewhere (Adams, 2006; Chew et al., 1996). We prefer to position female dogs and cats in dorsal recumbency and male dogs in lateral recumbency for laser lithotripsy. The area around the vulva or prepuce is clipped to remove surrounding hair and prepped for aseptic introduction of the cystoscope into the urethra and bladder. During cystoscopy irrigation of sterile warmed normal saline is used to distend the urinary tract and facilitate cystoscope passage. Once the uroliths are visualized in the urethra or bladder, a flexible quartz laser fiber is advanced through the working channel of the scope and connected to the laser unit.

To achieve optimum fragmentation of the urolith, the quartz fiber tip must be guided with the aid of a cystoscope so that it is in direct contact with the surface of the urolith before laser activation. During laser lithotripsy continuous irrigation of warmed sterile normal saline serves to absorb stray laser energy and flush urolith debris and fragments out of the visual field to maintain visibility. We use initial power and frequency settings of 0.5 to 0.7 joules per pulse and 6 to 10 Hz for laser lithotripsy. Increasing the frequency of laser pulses (Hz) increases the efficiency of urolith fragmentation but decreases the operator's potential reaction time in the event that the laser fiber tip inadvertently contacts the urothelium. Therefore the lowest laser settings that result in effective urolith fragmentation should be used during laser lithotripsy.

During laser activation the energy is limited to an area directly in front of the quartz laser fiber tip. An aiming beam within the visible spectrum is used to facilitate targeting the laser energy. The laser fiber should not be aimed directly at the mucosal surface and should be kept 0.5 mm or more away from the mucosal surface during laser activation. Therefore it is preferable to apply laser energy to the urolith surface while working parallel rather than perpendicular to the mucosa (see Figs. 204-1 and 204-2). In the event of brief laser application directly to the mucosal surface, mucosal injury is usually limited to superficial damage and associated bleeding. When in contact with the mucosal surface, the Ho:YAG laser is capable of making incisions into the bladder or urethral wall; perforation is possible during laser lithotripsy. The Ho:YAG laser can be used effectively in contact mode to remove small pedunculated polyps or tumors within the urinary tract without creating full-thickness incisions. With proper technique the risk of bladder or urethral perforation is minimal during laser lithotripsy.

Once uroliths are fragmented so that the fragments are small enough to pass through the urethra, larger fragments are removed initially with a stone basket to verify that the fragments are small enough to allow removal by antegrade voiding. Urolith fragments retrieved with stone baskets using aseptic technique should be submitted for bacterial culture and quantitative urolith analysis. If the larger fragments were safely retrieved through the urethra, voiding urohydropulsion is performed to evacuate remaining fragments.

Because of their larger urethral diameter, laser lithotripsy is successful in most female dogs and cats, and all stone fragments can be removed from the lower urinary tract. When all urolith fragments are documented to have been removed, the patient is considered stone free. Transurethral cystoscopy and laser lithotripsy results in stone-free status in approximately 80% of male dogs and 100% of female dogs (Adams and Lulich, 2006). In some male dogs laser lithotripsy of urethroliths may be followed by cystotomy to remove larger urocystoliths.

INDICATIONS FOR LASER LITHOTRIPSY

Minimally invasive removal of urethrocystoliths via laser lithotripsy is possible for female dogs and cats and for most male dogs larger than approximately 6 kg of body weight. With additional training and experience, laser fragmentation of ureteroliths and nephroliths in larger dogs is also feasible.

In male dogs the narrow urethral diameter along with curved course of the urethra around the ischial arch effectively limits the size of dog in which a transurethral approach is possible. The dog's size along with the size and number of uroliths that must be fragmented and removed transurethrally are considered to determine if male dogs are suitable candidates for laser lithotripsy. Alternative minimally invasive approaches for removal of urocystoliths in small male dogs include percutaneous cystoscopy, laparoscopic-assisted cystoscopy, and SWL fragmentation of bladder stones followed by voiding urohydropropulsion. Laser lithotripsy via transurethral approach may not be the best option for removal of very large stone burdens in male or female dogs because of the volume of fragments that must be flushed through the urethra following laser fragmentation.

ADVANTAGES OF LASER LITHOTRIPSY

Laser lithotripsy offers many advantages for urolith removal when compared to surgical approaches. One significant advantage of minimally invasive stone removal is reduced postprocedural dysuria and hematuria. Therefore owner preference plays a significant role when choosing whether to remove urocystoliths by open cystotomy or minimally invasive techniques such as laser lithotripsy. Laser lithotripsy can rapidly correct life-threatening urethral obstruction caused by uroliths. In fact, the procedural time is often shorter than surgery. Because cystoscopy can be performed safely immediately following cystotomy, uroliths not completely removed surgically can be fragmented and basketed without an additional incision (see Chapter 203). Dogs with recurrent uroliths may be managed repeatedly with laser lithotripsy via a transurethral approach to avoid repeated cystostomy. We have performed laser lithotripsy three times over a 23-month period in one male dog with recurrent calcium oxalate urolithiasis.

CONTRAINDICATIONS TO LASER LITHOTRIPSY

One relative contraindication to transurethral laser lithotripsy is the presence of an active urinary tract infection.

Because increases in intravesicular pressure during voiding urohydropropulsion may induce vesicoureteral reflux (and contribute to ascending pyelonephritis), urinary tract infections should be controlled with antimicrobics before lithotripsy. With an active urinary tract infection, small perforations of the bladder wall also could spread microorganisms into the abdominal cavity. Perioperative antimicrobics should be administered to dogs or cats with any history of current or prior urinary tract infection, because fragmentation of infected uroliths may liberate viable bacteria from the inner layers of the urolith.

Other contraindications to transurethral laser lithotripsy include coagulopathy and obstruction of the urinary outflow distal to the urolith (e.g., urethral stricture). With coagulopathies transurethral passage of the cystoscope and laser lithotripsy may result in intraluminal or periurethral hemorrhage. Therefore coagulopathies should be resolved if possible before attempting laser lithotripsy. Urethral strictures may preclude the passage of the cystoscope and make removal of urolith fragments more difficult because of the narrow urethral lumen through the strictured region.

POTENTIAL COMPLICATIONS OF TRANSURETHRAL LASER LITHOTRIPSY

Complications resulting from laser lithotripsy have been uncommon. The most common complication seen during prolonged transurethral cystoscopy is swelling of the urethral mucosa, which becomes particularly important in male dogs because of the narrow diameter of the urethral lumen. Acute mucosal swelling may preclude transurethral passage of the flexible ureteroscope in and out of the urinary bladder and prevent complete urolith fragmentation and removal. If this occurs, allowing 1 to 3 days for the urethral swelling to resolve may permit complete urolith removal. Urethral swelling may also result in transient outflow obstruction in some dogs after prolonged transurethral laser lithotripsy procedures.

Mucosal bleeding during laser lithotripsy may result in extravasation of blood and formation of blood clots within the bladder lumen. Blood clots tend to trap smaller urolith fragments against the mucosal surface, which may preclude complete removal of all fragments by voiding urohydropropulsion. In humans "second-look" procedures (such as percutaneous nephroscopy) are often used to remove any residual urolith fragments 1 to 2 days after the initial minimally invasive urolith removal technique. Similarly, second-look cystoscopy and voiding urohydropropulsion are required in some dogs and cats after laser lithotripsy.

Because Ho:YAG laser energy can be used to incise tissues, laser perforation of the urethra or bladder is possible. Given the small diameter of the quartz laser fibers, small-diameter holes caused by laser perforation of the bladder or urethra most likely can be resolved by placing an indwelling transurethral catheter and keeping the urinary tract decompressed for 3 to 5 days. If laser perforation is suspected, retrograde contrast studies should be used to document any leakage from the urinary tract and to confirm that the perforation has healed before removal of the indwelling urinary catheter.

Another potential source of complications from trans-urethral laser lithotripsy and removal of the fragments is trauma to the bladder or urethra during voiding urohydropropulsion to remove the urolith fragments. Transient urethral obstruction may occur when large numbers of urocystolith fragments are voided simultaneously through the urethra. If this occurs, repeat laser fragmentation of fragments within the urethral lumen can be used to resolve the obstruction. In addition, excessive intravesicular pressure applied to the bladder during transient urethral obstruction (in an attempt to flush out urolith fragments) could lead to bladder perforation. Proper voiding urohydropropulsion technique is required to prevent this complication.

SWL fragments stones mechanically, whereas laser fragmentation relies on a photothermal mechanism, possibly inducing chemical alterations in stone composition (Chan et al., 1999). This difference is not clinically relevant for most stone types; however, laser lithotripsy converts uric acid uroliths to small quantities of cyanide. Although cyanide can be absorbed into systemic circulation, the risk of clinical toxicity is very low (Teichman et al., 1998). We have safely removed uric acid uroliths from several dogs and one cat without complications related to cyanide toxicity. Our attempts to detect cyanide production in the effluence during cystoscopy and lithotripsy have been unsuccessful. Nonetheless, constant irrigation of saline and frequent evacuation of the urinary bladder during the procedure are recommended to prevent cyanide from potentially accumulating in higher concentrations.

Management of Feline Nonobstructive Idiopathic Cystitis

JOHN M. KRUGER, *East Lansing, Michigan*
CARL A. OSBORNE, *St. Paul, Minnesota*

In approximately 65% of nonobstructed male and female cats with naturally occurring lower urinary tract disease, the exact cause(s) of hematuria, dysuria, pollakiuria, stranguria, and periuria (urinating outside the litter box) are still unknown. After appropriate diagnostic evaluations, these cats are classified as having idiopathic feline lower urinary tract disease, idiopathic cystitis, or interstitial cystitis. In the past four decades over 70 agents or procedures have been recommended for management of nonobstructive idiopathic cystitis in cats; yet fewer than 10% of these proposed treatments have been evaluated in controlled clinical trials (Box 205-1). Debate surrounding the efficacy of various treatments is complicated by the self-limiting nature of clinical signs associated with the majority of cases of idiopathic cystitis. In this setting any form of therapy might appear to be beneficial as long as it is not harmful. The self-limiting nature of clinical signs in many cats with idiopathic cystitis underscores the need for controlled prospective double-blind clinical studies to prove the efficacy and safety of various forms of therapy.

BIOLOGIC BEHAVIOR

Periuria, pollakiuria, stranguria, and gross hematuria are the most common clinical signs observed in cats with nonobstructive idiopathic cystitis. Remarkably these clinical signs subside within 5 to 7 days (without therapy) in up to 92% of cats with acute nonobstructive idiopathic cystitis (Barsanti et al., 1982, Kruger et al., 2003; Osborne et al., 1996). Signs may recur after variable periods of time and again subside without treatment. Approximately 40% to 50% of cats with acute idiopathic cystitis experience recurrence of signs within 1 to 2 years (Barsanti et al., 1982; Kruger et al., 2003). Our impression is that recurrent episodes of acute idiopathic cystitis tend to decrease in frequency and severity as the cats become older (Kruger et al., 2003). Although recurrent clinical signs in patients with idiopathic cystitis are often assumed to be recurrence of the original disease, they may also be the result of a delayed manifestation of the original disease (e.g., spontaneous or iatrogenic urethral stricture) or onset of a different lower urinary tract disease associated with similar clinical signs (e.g., urolithiasis).

We have also encountered a small subset of cats with idiopathic cystitis in which clinical signs persist for weeks

to months or recur frequently. These cats are classified as having chronic idiopathic cystitis. In our experience fewer than 15% of cats evaluated because of acute idiopathic cystitis will develop chronic forms of the disease. Whether chronic idiopathic cystitis represents one extreme in the spectrum of clinical manifestations associated with similar etiologic factors or whether it represents an entirely different mechanism of disease than that associated with acute self-limiting idiopathic disease is unknown.

TREATMENT OF IDIOPATHIC CYSTITIS

Overview

Specific recommendations for management of cats with acute and chronic idiopathic cystitis ideally should be based on results of controlled clinical trials that document the efficacy and safety of therapeutic agents. We emphasize that all of the following general recommendations for treatment of nonobstructive idiopathic cystitis have not been substantiated by experimental and/or clinical investigations. Some of our recommendations are based on our uncontrolled clinical observations and personal opinions and should be considered within this framework.

Management of cats with nonobstructive idiopathic cystitis should encompass (1) thorough diagnostic evaluation to exclude other causes of lower urinary tract disease (Table 205-1); (2) client education emphasizing the biologic behavior of the disease and lack of controlled studies demonstrating efficacy of proposed therapies; (3) strategies to minimize urethral obstruction; (4) consideration of use of pharmacologic agents to reduce the severity and duration of clinical signs; (5) strategies to minimize risk of recurrence; and (6) prevention of iatrogenic disease. We approach treatment of cats with acute idiopathic cystitis by (1) emphasizing client understanding of the disease, and (2) minimizing the risk of recurrence through use of long-term dietary and environmental management strategies. Short-term use of pharmacologic agents is considered for any patient with severe clinical signs. Long-term pharmacologic interventions usually are reserved for cats with more severe chronic forms of the disease in which dietary and environmental management strategies have failed to adequately control clinical signs or frequency of recurrences.

Box 205-1

Therapeutic Agents or Procedures Advocated by Veterinarians for Management of Nonobstructive Feline Idiopathic Cystitis Over a 3-Year Period From 2003 To 2005**Antiinflammatories/Analgesics**

- Prednisolone*
- Methylprednisolone
- Dexamethasone
- Piroxicam
- Meloxicam
- Ketoprofen
- Carprofen
- Tolfenamic acid
- Tepoxalin
- DMSO
- Zafirlukast
- Montelukast
- Butorphanol
- Buprenorphine
- Oxymorphone
- Fentanyl
- Tramadol

Environmental Management

- Environmental enrichment
- Litter box management
- Facial pheromone*

Antidepressants/Anxiolytics

- Amitriptyline*
- Nortriptyline
- Imipramine
- Clomipramine
- Fluoxetine
- Paroxetine
- Diazepam
- Oxazepam
- Alprazolam
- Buspirone

Antispasmodics

- Propantheline*
- Oxybutynin
- Aminopentamide
- Atropine
- Acepromazine
- Prazosin
- Phenoxybenzamine
- Dantrolene
- Flavoxate

Antimicrobics

- Doxycycline
- Enrofloxacin
- Amoxicillin
- Amoxicillin/clavulanate

Dietary Management

- Canned diets*
- Acidifying diets
- Hypoallergenic diets
- Omega 3 fatty acids
- Supplemental water

Glycosaminoglycans

- Pentosan polysulfate
- Glucosamine*
- Chondroitin sulfate
- Polysulfated glycosaminoglycans
- Hyaluronate

Miscellaneous

- Parenteral fluids*
- Furosemide
- Megestrol acetate
- Hydroxyzine
- Cyproheptadine
- Trimeprazine
- Cromolyn
- Arginine
- Hydrodistention

Alternative Medicine

- Acupuncture
- Colloidal silver
- Cantharis
- Terebinthina
- Marshmallow root
- Parsley root
- Uva ursi leaf
- Corn silk
- Dandelion
- Polyporus mushroom
- Others

*Indicates therapies that have been evaluated by controlled clinical trials.

Antimicrobial Agents

Antimicrobial agents commonly have been used for decades as empiric therapy for hematuria, dysuria, and pollakiuria in cats. However, the infrequency (1% to 3%) with which bacteria have been identified at the onset of clinical signs of lower urinary tract disorders in young to middle-aged cats has been well established. The uselessness of antimicrobial agents in the treatment of abacteriuric cats with lower urinary tract disease also has been

documented (Barsanti et al., 1982). Widespread empiric use of antimicrobial agents for treatment of cats with lower urinary tract signs may have been perpetuated at least in part by misinterpretation of “pseudobacteria” observed in unstained urine sediment and failure to perform diagnostic quantitative urine cultures to confirm bacterial urinary tract infection. In a recent study in our laboratory, up to 89% of unstained feline urine sediments reported as positive for bacteriuria by light microscopy were found to be sterile when compared to results of quantitative

urine culture. Staining of urine sediment with a modified Wright-stain procedure (Diff Quik) significantly reduces the frequency of false-positive bacteriuria.

Amitriptyline and Other Antidepressants

Amitriptyline hydrochloride (Elavil, Astra-Zeneca Pharmaceuticals) has been advocated for the treatment of severe recurrent idiopathic cystitis in cats. Amitriptyline is a tricyclic antidepressant drug with anticholinergic, antihistaminic, sympatholytic, analgesic, and antiinflammatory properties. In humans several weeks to months of treatment are often necessary before the antidepressant actions of amitriptyline are clinically evident. In contrast, the anticholinergic, antihistaminic, sympatholytic, analgesic, and antiinflammatory effects of amitriptyline and other tricyclic antidepressants are more rapid in onset (often within several days). Consequently amitriptyline and other tricyclic antidepressants have been used in humans for treatment of various nonpsychiatric conditions. Amitriptyline has been used extensively for treatment of humans with interstitial cystitis. In a recent randomized placebo-controlled, double-masked study of amitriptyline for treatment of interstitial cystitis in humans, 63% of patients receiving amitriptyline for 4 months rated satisfaction with the therapeutic outcome as good or excellent compared to only 4% of patients receiving a placebo. In an uncontrolled study of cats with severe recurrent idiopathic cystitis, clinical signs decreased in 9 of 15 (60%) cats treated with amitriptyline for 6 months (Chew et al., 1998). However, in a randomized double-masked, placebo-controlled clinical trial to evaluate the efficacy of short-term (7-day) amitriptyline therapy in ameliorating clinical signs in 31 cats with acute nonobstructive idiopathic cystitis, amitriptyline did not appear to reduce the duration of pollakiuria

and hematuria (Kruger et al., 2003). In addition, clinical signs recurred sooner and with higher frequency in amitriptyline-treated cats than in cats receiving a placebo. Adverse events associated with amitriptyline treatment included urinary tract infection, sedation, hyperbilirubinemia, and increased serum alanine aminotransferase (ALT) activity. In another placebo-controlled study of cats with idiopathic cystitis performed by other investigators, differences were not observed in the magnitude of change in severity of clinical signs after short-term (7-day) treatment with amitriptyline and amoxicillin compared to a placebo and amoxicillin (Kraijer, Fink-Gremmels, and Nickel, 2003).

These results suggest that short-term (7-day) amitriptyline treatment is of little benefit in resolving pollakiuria and hematuria in cats with acute idiopathic cystitis. However, the apparent lack of beneficial effects of short-term administration does not preclude the possibility that long-term amitriptyline administration may be of value for cats with more severe or persistent forms of idiopathic cystitis. Pending results of controlled clinical trials, we reserve amitriptyline for cats with severe chronic idiopathic cystitis who have not responded to other forms of pharmacologic, dietary, and environmental management (Table 205-2). If improvement in clinical signs is not observed after 2 to 4 months of therapy, the dosage of the drug should be tapered gradually over several weeks and then stopped. In humans abrupt discontinuation of tricyclic antidepressants may result in a withdrawal syndrome characterized by gastrointestinal, somatic, neurologic, and psychiatric disturbances. The efficacy and safety of other tricyclic antidepressants, selective serotonin reuptake inhibitors, and anxiolytics advocated for management of chronic or frequently recurrent forms of idiopathic cystitis have not been evaluated by controlled clinical trials (see Table 205-2).

Agent	Properties	Dose*	Controlled Trial?	INDICATIONS AND OUR FORECAST†		Adverse Effects/Special Considerations
				Acute FIC	Chronic FIC	
Butorphanol (Torbugesic)	Analgesic	0.2-0.4 mg/kg q8h PO for 1-3 days	NR	++		Sedation, ataxia, anorexia, diarrhea
Buprenorphine (Buprenex)	Analgesic	0.01-0.02 mg/kg q6-12h IM, SQ, buccally for 1 to 3 days	NR	++		Sedation, respiratory depression
Fentanyl (Duragesic)	Analgesic	1.25-2.5 mg q72h transdermally	NR	+		Respiratory depression, bradycardia, urine retention, constipation, dysphoria, agitation
Tramadol (Ultram)	Analgesic	ND (4 mg/kg q12h PO for 1-3 days)	NR	+		Respiratory depression, anorexia, constipation, diarrhea, behavior changes; avoid concurrent administration of antidepressants; combination product containing acetaminophen (Ultracet, Ortho-McNeil Pharmaceutical) is contraindicated in cats
Tolteridine (Detrol)	Anticholinergic, antispasmodic	ND (0.05 mg/kg q12h PO)	NR	+	+	Vomiting, diarrhea, constipation, urine retention, sedation; amitriptyline may potentiate adverse effects
Pentosan polysulfate (Elmiron)	GAG analog	50 mg q12h PO	NR		+	Diarrhea, vomiting (rare)
Chondroitin sulfate/Glucosamine hydrochloride	GAG/GAG precursor	Chondroitin sulfate 8.8 mg/kg 22/Glucosamine HCl 22 mg/kg q24h PO	NR		+	Gastrointestinal upset (rare)
Amitriptyline (Elavil)	Antidepressant, sympatholytic, Anticholinergic, antihistamine, analgesic	5-12.5 mg q12-24h PO	Yes (acute) NR (chronic)		++	Sedation, weight gain, urine retention, urolith formation, UTI, increased liver enzymes; avoid short-term use or rapid discontinuation
Clomipramine (Clomicalm)	Antidepressant, sympatholytic, anticholinergic, antihistamine, analgesic	0.5 mg/kg q24h PO	NR		+	Sedation, vomiting, diarrhea, anticholinergic effects; avoid short-term use or rapid discontinuation
Buspirone (BuSpar)	Anxiolytic	2.5-5 mg q12h PO	NR		+	Sedation (rare), behavior changes
Fluoxetine (Prozac)	Antidepressant	0.5-1 mg/kg q24h PO	NR		+	Diminished appetite, vomiting, lethargy, anxiety, irritability, sleep disturbances

GAG, Glycosaminoglycan; IM, intramuscularly; ND, not determined; NR, not reported; PO, orally; SQ, subcutaneously; UTI, urinary tract infection.

*Values in parentheses indicate an approximate dose extrapolated from human dosages.

†Our predictions of efficacy if agent was evaluated by a controlled clinical trial: +++ highly effective; ++ moderately effective; + occasionally effective.

Antiinflammatory Agents and Analgesics

Mucosal ulceration and submucosal edema, hemorrhage, fibrosis, neovascularization, mastocytosis, and mononuclear inflammatory cell infiltration are common light microscopic lesions observed in the urinary bladders of cats with chronic idiopathic cystitis. These abnormalities are consistent with inflammation. However, the specific cause(s) of inflammation in many cats with idiopathic cystitis is (are) unknown. The lack of specific therapy for cats with idiopathic cystitis has resulted in widespread use of antiinflammatory agents in an attempt to reduce the severity of inflammation-associated clinical signs. Unfortunately there have been few controlled clinical trials to study the short- and long-term effectiveness of antiinflammatory agents in the symptomatic treatment of pollakiuria and hematuria in cats.

Glucocorticoids

By virtue of their potent antiinflammatory properties, glucocorticoids are a logical therapeutic choice to minimize pollakiuria and hematuria in cats with idiopathic cystitis. However, results of a small, double-blind, placebo-controlled study of untreated male and female cats with idiopathic cystitis indicated that antiinflammatory doses of prednisolone (1 mg/kg orally q12h for 10 days) was of no benefit in reducing the severity or duration of clinical signs in affected cats (Osborne et al., 1996). Clinical signs subsided within 1 to 2 days in both prednisolone (n=6)– and placebo (n=6)– treated cats; urinalysis abnormalities of hematuria and pyuria subsided in approximately 2 to 5 days in both groups.

Nonsteroidal Antiinflammatory Drugs

Nonsteroidal antiinflammatory drugs (NSAIDs) are widely used for their antiinflammatory and analgesic properties in veterinary and human medicine. Although generally considered mild analgesics, NSAIDs may be more effective in settings in which inflammation has caused sensitization of pain receptors to normally painless mechanical and chemical stimuli. NSAIDs have been used for management of mild discomfort in humans with interstitial cystitis. Similarly the NSAIDs meloxicam, ketoprofen, tolafenamic acid, and piroxicam have been recommended for treatment of dysuria and inflammation in cats with idiopathic cystitis. However, the safety and efficacy of NSAIDs in the treatment of either humans with interstitial cystitis or cats with idiopathic cystitis have not been evaluated by controlled clinical trials. It is noteworthy that certain NSAIDs have been associated with sterile hemorrhagic cystitis in humans and have been shown to induce histopathologic lesions typical of interstitial cystitis in rodents. Pending further safety and efficacy studies, one must use appropriate caution when considering use of NSAIDs to treat feline idiopathic cystitis.

Opioid Analgesics

Narcotic analgesics are often used for initial management of severe visceral pain in humans with interstitial cystitis. Similarly the opiate agonists butorphanol, buprenorphine, fentanyl, and tramadol have been advocated for short-term

analgesia in cats with idiopathic cystitis (see Table 205-2). Our anecdotal observations and those of others suggest that short-term opioid analgesic therapy for 24 to 72 hours may be of benefit in alleviating acute “flare-ups” of severe pollakiuria, dysuria, stranguria, and periuria in cats with idiopathic cystitis. In addition, combination of an opioid analgesic and a short-term tranquilizer (e.g., acepromazine) may facilitate collection of urine specimens for urinalysis and culture from acutely symptomatic cats. However, we emphasize that there have been no reports of controlled studies evaluating the efficacy and safety of short-term opioid analgesics for management of cats with idiopathic cystitis.

Anticholinergics and Antispasmodics

Pollakiuria is a common feature of feline idiopathic cystitis. Inappropriate voiding of urine occurs at low volumes of bladder filling and may be associated with sensations of pain, bladder fullness, and urgency. Presumably, pollakiuria is the result of inflammation-induced stimulation of urinary bladder sacral sensory afferent nerves. Sensations of pain and perception of fullness and urgency induce a premature micturition reflex and subsequent inappropriate or involuntary voiding of small quantities of urine. Because cholinergic parasympathetic efferents are normally responsible for detrusor contraction, anticholinergics agents may logically be considered as symptomatic treatment of pollakiuria and urge incontinence.

The quaternary ammonium anticholinergic agent propantheline (Pro-Banthine, Schiapparelli Searle) is a potent nonselective muscarinic antagonist that minimizes the force and frequency of uncontrolled detrusor contractions. However, the clinical use of propantheline has been limited by lack of selectivity for urinary bladder compared to other smooth-muscle organs. In a controlled clinical study of the efficacy of propantheline (7.5 mg given orally on one occasion) for treatment of acute nonobstructive idiopathic cystitis, no difference in rate of recovery was observed between cats treated with propantheline and control groups (Barsanti et al., 1982). Potential adverse effects include urinary retention, tachycardia, vomiting, and constipation. Unfortunately the optimal dose and maintenance intervals for cats have not been determined. Further studies using appropriate doses are required to substantiate a beneficial symptomatic effect of propantheline in cats with idiopathic cystitis.

Oxybutynin chloride (Ditropan, Alza Corp.) and tolterodine (Detrol, Pfizer US Pharmaceuticals) are synthetic tertiary amine muscarinic receptor antagonists used for management of overactive bladder and urge incontinence in humans, dogs, and cats (see Table 205-2). Oxybutynin is a moderately potent anticholinergic agent with additional independent musculotropic relaxant and local anesthetic effects. As a result, intravesicular oxybutynin has been used for symptomatic management of human interstitial cystitis. Although tolterodine is a pure muscarinic antagonist, pharmacologic studies in healthy anesthetized cats indicate that it has a significantly more pronounced *in vivo* effect on urinary bladder than on salivary gland, whereas oxybutynin has greater selectivity for salivary gland (Nilvebrant et al., 1997). It is

tempting to speculate that tolterodine may be of value in reducing pollakiuria associated with feline idiopathic cystitis. However, controlled studies evaluating the efficacy of oxybutynin or tolterodine in reducing the magnitude of pollakiuria in cats with idiopathic cystitis have not been reported. Potential adverse effects associated with tolterodine or oxybutynin administration include vomiting, diarrhea, constipation, urine retention, and sedation. Coadministration of oxybutynin or tolterodine with other anticholinergic agents (e.g., amitriptyline) may intensify adverse effects and should be avoided.

Glycosaminoglycans

Transitional epithelium of the urinary bladder is covered by a glycocalyx composed of hydrated glycoconjugates, including glycoproteins and glycosaminoglycans (GAGs). Urothelial GAGs minimize adherence of microorganisms and crystals to the bladder urothelium and limit movement of urine proteins and other ionic and nonionic solutes from the bladder lumen into surrounding tissues. Quantitative or qualitative defects in surface GAGs and subsequent increased urothelial permeability have been hypothesized to be causative factors in the pathogenesis of feline idiopathic cystitis and human interstitial cystitis.

Pentosan Polysulfate

Oral or intravesicular administration of GAGs is commonly used to manage interstitial cystitis in humans. Pentosan polysulfate sodium (Elmiron, Ortho-McNeil Pharmaceutical) is a semi-synthetic low-molecular weight heparin analog that reinforces urothelial GAGs and reduces transitional cell injury. Pentosan polysulfate is the only oral medication approved by the Food and Drug Administration for treating interstitial cystitis in humans in the United States. Symptomatic remission was observed in 28% to 40% of humans with interstitial cystitis treated with oral or intravesicular pentosan polysulfate sodium compared to 13% to 20% remission in patients treated with a placebo. Maximum benefit in overall improvement in pain and urgency in humans with interstitial cystitis was noted after 6 to 11 months of therapy. Prolongation of prothrombin time, epistaxis, gingival bleeding, alopecia, abdominal pain, diarrhea, and nausea have been observed uncommonly in humans treated with pentosan polysulfate. Our empiric clinical impression and the impression of others is that oral or parenteral pentosan polysulfate may benefit some cats with chronic idiopathic cystitis (see Table 205-2). Results of controlled clinical studies evaluating the safety and efficacy of pentosan polysulfate for treatment of feline idiopathic are warranted.

Glucosamine and Chondroitin Sulfate

Glucosamine, an amino sugar naturally produced in the body, is an important intermediate for the formation of GAGs. Chondroitin sulfate is one of the most abundant GAGs in the bladder surface GAG layer. Oral glucosamine and intravesicular chondroitin sulfate have been reported to have moderate beneficial effects in uncontrolled studies of humans with interstitial cystitis. Anecdotally oral glucosamine alone or in combination

with oral chondroitin sulfate has been of apparent benefit to some cats with chronic forms of idiopathic cystitis (see Table 205-2). However, a recent 6-month randomized placebo-controlled clinical trial of oral glucosamine in cats with idiopathic cystitis did not reveal any significant difference between the severity of clinical signs in cats treated with glucosamine and those treated with a placebo (Gunn-Moore and Shenoy, 2004). The efficacy of oral glucosamine combined with chondroitin sulfate for management of cats with idiopathic cystitis has not been evaluated. Because of potential synergy between glucosamine and chondroitin sulfate, a randomized controlled, double-masked clinical trial is clearly warranted.

Dietary Management

Unless complicated by other illness, cats with idiopathic cystitis typically have concentrated and acidic urine. The prevalence and magnitude of crystalluria are variable. However, the prevalence of crystalluria in cats with idiopathic cystitis does not differ significantly from that of unaffected cats. Although crystalluria per se does not appear to be a risk factor for nonobstructive idiopathic cystitis, it has been hypothesized that high concentrations of normal and/or abnormal components in urine may be toxic to urinary bladder tissues in affected cats. The comparative effects of wet and dry forms of a diet designed to lower urine pH on the frequency of recurrence signs in cats with idiopathic cystitis was evaluated in a nonrandomized, open, prospective study (Markwell et al., 1999). Signs of lower urinary tract disease recurred in 11 of 28 (39%) cats fed the dry diet and in 2 of 18 (11%) cats fed the canned diet. Although the basis for the beneficial response associated with the canned diet was not determined, cats consuming the canned diet had a significantly lower urine specific gravity than those consuming the dry diet. Based on these results and until other randomized controlled studies are available, we routinely recommend increasing dietary water intake by feeding canned food or by use of other strategies designed to increase water consumption (Westropp, Buffington, and Chew, 2005).

Urethral obstruction is a potentially life-threatening sequela in cats with idiopathic cystitis that may result from formation of matrix-crystalline urethral plugs. Because insoluble microscopic crystals appear to be an integral part of many matrix-crystalline urethral plugs encountered in male cats, using medical protocols to prevent crystal formation in patients at risk for urethral obstruction is logical. Struvite is the primary mineral component of most urethral plugs, although other mineral types may be encountered. Successful prevention of recurrent urethral obstruction caused by struvite-containing urethral plugs using diets to reduce urine pH and urine magnesium and phosphorous concentrations has been reported.

Stress Management

Clinical observations suggest that stress may play a role in precipitating or exacerbating signs associated with

idiopathic cystitis. Neuroendocrine abnormalities identified in cats with chronic idiopathic cystitis are indicative of increased activity of the sympathetic nervous system and diminished adrenocortical responsiveness (Westropp, Buffington, and Chew, 2005). Based on these observations, therapeutic strategies designed to normalize reactivity of the stress response system have been advocated as primary therapy for prevention and recurrence of feline idiopathic cystitis.

Environmental Enrichment

Environmental enrichment for indoor-housed cats entails providing necessary resources (food, water, litter boxes, space, play), refining cat-owner interactions, managing conflict, and minimizing the impact of change (Westropp, Buffington, and Chew, 2005). Although the ease, safety, and economy of these activities are appealing, controlled studies evaluating the efficacy of environmental enrichment strategies for management of idiopathic cystitis have not been reported.

Facial Pheromone

Feline facial pheromone fraction F3 (Feliway, Veterinary Products Laboratories) is a synthetic pheromone that was developed for management of anxiety-related behaviors in cats. Application of pheromones to the living environment has been recommended as adjunctive therapy to environmental enrichment for management of cats with idiopathic cystitis. However, a recent randomized double-blind, placebo-controlled, crossover study of nine cats with idiopathic cystitis treated for 2 months with feline facial pheromone or a placebo did not reveal significant differences in severity of clinical signs, behavior, or overall health between treatment groups (Gunn-Moore and Cameron, 2004).

Urethral Obstruction in Cats

KENNETH J. DROBATZ, *Philadelphia, Pennsylvania*

Feline urethral obstruction is a relatively common complaint compromising approximately 10% of cats presenting to a large urban veterinary emergency service in a recent report (Lee and Drobatz, 2003). The most common cause of obstruction is a mucous or mucocrystalline plug secondary to feline lower urinary tract disease, although obstruction by calcium oxalate stones is becoming more frequent. The majority of cats presented with urethral obstruction are relatively stable, but approximately 12% have severe physiologic compromise with significant electrolyte and acid-base changes. In this latter group of patients the initial approach can make the difference between life and death in this relatively reversible condition. This chapter focuses on the initial evaluation, treatment, and monitoring of these physiologically dynamic and fragile patients.

CLINICAL SIGNS AND DIAGNOSIS OF URETHRAL OBSTRUCTION

The most common clinical sign specific to urethral obstruction is straining to urinate without passing any urine. This is often preceded by complaints such as excessive licking at the perineal area, vocalizing, pollakiuria, dysuria, hematuria, and urinating small amounts outside the litter box. The median duration of clinical signs is about 3 days, with the owner becoming concerned when the cat cannot pass urine despite prolonged attempts in the litter box. Many owners confuse the prolonged urinating posture as straining to defecate and complain that their cats are constipated or reluctant to walk. More severely affected cats become lethargic, stop eating, vomit, and become extremely weak. Some cats are found lying in their litter boxes, extremely weak and minimally responsive when the inability to pass urine is prolonged.

The diagnosis of urethral obstruction is relatively straightforward when the cat is presented with a history of straining to urinate and a large, firm urinary bladder is palpated. Care should be taken not to apply too much pressure to a severely distended urinary bladder because the bladder wall may be compromised as a result of prolonged ischemia. A more challenging diagnosis is when astute owners bring their cat in for straining to urinate early on before bladder distention has become excessive. In these instances the urinary bladder may be mildly-to-moderately distended but cannot be expressed.

FLUID BALANCE, TISSUE PERFUSION, AND INITIAL DATABASE

Because of the severe fluid deficits and dramatic electrolyte changes that develop, cardiovascular compromise is the

most common and immediate life-threatening sequela to urethral obstruction. The initial physical evaluation should focus on assessment of mucous membrane color, capillary refill time, pulse quality and rate, and cardiac auscultation. An inappropriate slow heart rate indicates clinically significant hyperkalemia and should prompt immediate electrocardiogram (ECG) evaluation and measurement of serum potassium. However, it also should be noted that in cats life-threatening hyperkalemia also can be associated with a normal to rapid heart rate.

To optimize tissue oxygen delivery, supplemental oxygen via mask or flow-by should be administered; and intravenous access should be obtained to facilitate emergency drug therapy, fluid administration, and collection of blood. An emergency database ideally includes packed cell volume (PCV), total solids (TS), blood glucose, dipstick blood urea nitrogen (BUN), sodium, potassium, ionized calcium, and a venous blood gas. Both serum BUN and creatinine can be severely elevated in cats with obstructive uropathy; however, these values are not prognostic per se and often return to normal levels within a few days. A lead II ECG should be reviewed for hyperkalemia-induced cardiac conduction abnormalities. ECG abnormalities consistent with hyperkalemia include tall positive or large negative T-waves, diminished or absent P-waves, prolonged P-R intervals, widened QRS complexes, and sine waves. The sine wave is an end-stage ECG finding that develops when the QRS and T waves merge. Rarely ventricular tachycardia can be seen in cats with hyperkalemia; however, sinoventricular rhythm with intraventricular conduction delay may be misinterpreted as ventricular tachycardia. Although textbooks describe characteristic ECG findings developing with specific, progressively increased blood potassium concentrations, the association is inconsistent clinically. Some cats are hyperkalemic without exhibiting major ECG changes. Conversely, when ECG changes are observed, clinically significant hyperkalemia is present.

Physical assessment, oxygen administration, ECG evaluation, and intravenous access should occur within minutes of presentation; fluid administration can then be initiated quickly. Although potassium-free solutions such as 0.9% saline are recommended in cats with urethral obstruction, any balanced electrolyte solution suffices to provide vascular volume support and does not contribute substantially to the potassium concentration on an acute basis. Theoretically administration of 0.9% saline contributes to the metabolic acidosis in obstructed, dehydrated cats. In a recent randomized clinical trial at

our hospital, 0.9% saline was slower to correct metabolic acidosis in critically ill cats with urethral obstruction when compared to Normsol-R (Abbott Laboratories), but the outcome was similar between the two treatments. The dilution provided by 0.9% saline or a balanced electrolyte solution helps to lower the potassium concentration but does not lower it rapidly enough in patients that are affected by the hyperkalemia. I recommend administering 20 to 30ml/kg of body weight as an intravenous bolus and monitoring tissue perfusion status (mucous membrane color, capillary refill time, pulse quality) as fluid is being administered. I adjust the dose and administration rate, depending on the response to this fluid challenge, as well as the response to treatment of the electrolyte and acid-base abnormalities.

Rapid assessment of the emergency database results provides information for further therapy. A variety of electrolyte and acid-base derangements occur in critically ill cats with urethral obstruction, leading to significant physiologic consequences. The most important abnormalities are hyperkalemia, metabolic acidosis, and ionized hypocalcemia, often developing concurrently.

Hyperkalemia

Potassium concentration can be extremely high ($>10\text{mEq/L}$) in cats with urethral obstruction. The primary clinical concern is the effect of potassium on cardiac conduction. When ECG changes are recognized as described earlier, the potassium concentration is usually quite high; the clinician can also assume other electrolyte and acid-base changes to be severe as well. Since the severity of ECG signs does not always correlate with the magnitude of hyperkalemia, treatment should be guided by its functional consequences by monitoring the ECG. A cat with a high potassium concentration but no functional consequence does not require specific therapy for hyperkalemia and responds well to intravenous fluid therapy and relief of the urethral obstruction. A cat with cardiac conduction disturbances requires specific therapy directed at the hyperkalemia or its functional effects. Reversing the effects of hyperkalemia can be achieved by direct antagonism of the actions of the high potassium on the membrane potentials and by lowering the plasma potassium concentration. Plasma potassium concentration may be lowered by driving potassium intracellularly or by removal of potassium from the body.

Calcium gluconate directly antagonizes the cardiac effects of hyperkalemia. Administration of 50 to 100mg/kg of calcium gluconate intravenously over 2 to 3 minutes is recommended for the average cat, with continuous ECG evaluation (to observe for calcium-induced cardiac arrhythmias). The effects of calcium gluconate administration are immediate; thus it is the first drug of choice in cats that have significant cardiac rhythm disturbances caused by hyperkalemia. The effects last approximately 20 to 30 minutes.

Regular insulin at 0.1 to 0.25 unit/kg intravenous bolus promotes the intracellular movement of potassium. Insulin administration should be followed by a slow bolus of 1 to 2g of 25% glucose per unit of insulin given to prevent hypoglycemia. Plasma potassium concentration

should begin to decrease within several minutes to 1 hour. Blood glucose monitoring should be maintained for several hours after the administration of the insulin, and the intravenous fluids should be supplemented with glucose as needed to maintain normoglycemia.

Sodium bicarbonate administration can lower plasma potassium concentration by raising the pH and driving potassium into the cells (see the section that follows on Metabolic Acidosis). The effect on the plasma potassium concentration begins within 30 to 60 minutes and may persist for hours.

The effects of calcium, insulin and dextrose, and sodium bicarbonate are transient. The administration of these drugs buys the clinician time to remove the urethral obstruction and induce fluid diuresis to correct the underlying problem.

Metabolic Acidosis

Metabolic acidosis can be severe in critically ill cats with urethral obstruction. Blood pH drops below 7.0 in some cats. Severe acidosis (<7.0) can predispose the heart to ventricular arrhythmias, decrease cardiac contractility, decrease the inotropic response to catecholamines, and cause peripheral vasodilation, all of which may contribute to poor tissue perfusion.

The main treatments for metabolic acidosis include relief of obstruction, fluid diuresis, and bicarbonate therapy. The first two are usually adequate in the majority of cats. In the unstable cat with severe metabolic acidosis, administration of sodium bicarbonate should be considered. The formula recommended to approximate the total body deficit is $0.3 \times \text{body weight (kilograms)} \times \text{the base deficit}$. One third of this deficit should be given slowly intravenously (over approximately 15 minutes), and the rest placed in the intravenous fluids to be administered over several hours. (If blood gas analysis is not available, 1 to 2mEq/kg of sodium bicarbonate can be administered slowly to critically ill cats.) Rapid intravenous boluses of sodium bicarbonate should be avoided because of the production of CO_2 and its diffusion into the central nervous system, making cerebrospinal fluid acidosis even worse. In addition, because bicarbonate administration raises blood pH, sodium bicarbonate might lower the ionized calcium concentration (see following paragraphs). Bicarbonate should be administered after calcium supplementation in cats with very low blood-ionized calcium.

Ionized Hypocalcemia

Severe ionized hypocalcemia may occur in the more critically ill cats. Hypocalcemia exacerbates the effects of hyperkalemia on membrane excitability. Treatment of severe ionized hypocalcemia is reserved for cats that have clinical signs such as muscle stiffness, tetany, and cardiovascular disturbances. Treatment is similar to calcium gluconate therapy for hyperkalemia mentioned previously (50 to 100mg/kg of calcium gluconate intravenously over 2 to 3 minutes). Continuous ECG monitoring is recommended when administering calcium.

SEDATION FOR URETHRAL CATHETERIZATION

Ongoing resolution of metabolic derangements depends on catheterization and relief of urethral obstruction. The most severely affected (i.e., moribund) cats may not require sedation for urethral catheterization and are so compromised that administration of a sedative may result in death. In other cats mentation and responsiveness are improved after emergency stabilization; sedation may be required to provide a relatively stress-free urethral catheterization. Ketamine (5 to 10mg/kg intravenously [IV]) with diazepam (0.2 to 0.5mg/kg IV) or midazolam (0.2 to 0.5mg/kg IV) can be used. Alternatively butorphanol (0.2mg/kg) combined with diazepam (0.2 to 0.5mg/kg IV) or midazolam (0.2 to 0.5mg/kg IV) along with ketamine (2mg/kg IV) is preferred by some clinicians. The butorphanol or benzodiazepine doses may be repeated if passage of a urinary catheter is prolonged. Alternatively ongoing sedation can be maintained with propofol (small slow boluses of 2 to 4mg/kg IV titrated to effect). Respiratory rate should be monitored carefully when propofol is used since apnea can sometimes be a side effect when it is given too quickly. Ketamine should be avoided if cardiac abnormalities are detected on physical examination or if cardiac disease is suspected.

INSTRUCTIONS FOR URETHRAL CATHETERIZATION

Supplies needed for urethral catheterization include a sterile open-end 3.5-Fr tomcat catheter (Sovereign, Covidien), 3.5- or 5-Fr red rubber feeding tube (Sovereign, Tyco Health Care Group LP), sterile lubricating gel, sterile gloves, intravenous extension set, sterile 0.9% saline flush, several 10-ml syringes for flushing the urinary catheter, sterile urine collection bag, and sterile intravenous line for connection of indwelling urinary catheter to sterile urine collection bag (catheter adaptor, Becton Dickinson Co.).

The following are the usual steps taken to relieve the urethral obstruction. Position the cat in lateral or dorsal recumbency (based on the preference of the operator). Clip the hair on and around the prepuce and gently scrub the area as for a sterile procedure. Extrude the penis and pinch the prepuce to maintain extrusion. Clear any plugs from the tip of the penis (rarely this is the only source of obstruction). Using sterile technique, place the tip of the tomcat catheter into the tip of the penis. While maintaining the catheter in the tip of the penis, allow the penis to slip back into the prepuce. Pull the prepuce caudally and dorsally to "straighten out" the urethra and then gently advance the urinary catheter until resistance is encountered. Place the male end of the intravenous extension line onto the dilated end of the tomcat catheter. Place the 10-ml syringe filled with sterile saline flush onto the female end of the extension set and flush sterile saline into the urinary catheter. If resistance to flushing is encountered, slightly back the urinary catheter out until flushing can be continued. Slowly advance the urinary catheter again while flushing. If resistance to flushing is encountered again, slightly back the urinary catheter out

again until flushing can be continued. Repeat as needed multiple times. This gentle flushing eventually results in dislodgement of the urethral obstruction and successful passage of the urinary catheter into the urinary bladder. Be patient and remember to maintain adequate sedation during flushing.

Rarely a urinary catheter cannot be passed using the previous method. In this instance perform a cystocentesis, placing a 22-gauge needle in the ventral body of the bladder angled caudally. Drain the urinary bladder completely and then repeat the urethral flushing and catheterization procedure described. Relief of back pressure from the distended urinary bladder may now allow retrograde flushing of the urethral plug and passage of the urinary catheter. Be aware that cystocentesis is considered a back-up alternative for facilitating urinary catheterization because passing a needle into a urinary bladder with compromised blood flow and damaged tissue may contribute to urinary bladder rupture. Should the above methods fail, emergency perineal urethrostomy or temporary prepubic cystostomy has to be performed to allow for urine flow.

Once the urinary catheter tip is passed into the urinary bladder neck, drain the urine and flush the bladder multiple times with sterile saline. Slowly remove the tomcat catheter while continuing to flush saline through the catheter to maintain urethral patency. Then sterilely place the 5-Fr red rubber feeding tube into the urethra (a 3.5-Fr catheter is the second choice if the 5-Fr cannot be passed). Take care that the red rubber catheter is not placed too far into the urinary bladder since a knot in the catheter can develop as it follows the contour of the bladder wall. Suture (3-0 nylon) the catheter to the prepuce using a white tape butterfly around the urinary catheter where it exits the tip of the penis. Connect the red rubber catheter to the sterile intravenous line and connect the other end of the line to the sterile urine collection bag.

CONTINUED INPATIENT CARE

After initial stabilization continued monitoring of physical perfusion parameters, body temperature, mentation, continuous ECG, PCV, TS, dipstick glucose, dipstick BUN, serum sodium, serum potassium, ionized calcium concentration, acid-base status, and urine output should be done. Most cats do well if they remain stable after the first two hours. Post-obstructive diuresis can be profound, especially in the 24 to 48 hours following relief of the obstruction. Urine output may exceed 120ml/hour in some cats. Fluid therapy should be adjusted according to measured urine output, perfusion parameters, PCV, and TS. Once renal function has returned to near normal levels, it may be necessary to reduce the rate of fluid administration to insure continued diuresis is not iatrogenic. The most common electrolyte problem encountered after the initial stabilization period is hypokalemia. Many cats require potassium supplementation within several hours. Another (rare) complication of urethral obstruction is severe hematuria resulting in anemia. If the urine appears unusually bloody, a PCV should be performed on the urine, and the cat's peripheral blood PCV should be monitored closely. A transfusion is rarely required to maintain

the PCV and tissue perfusion at reasonable levels. Pain management is also important in the postobstructive period. Anecdotally butorphanol (0.1 mg to 0.2 mg/kg IV q6-8h) or buprenorphine (0.01 mg/kg IV q6-12h) appears to work well. An Elizabethan collar should be placed to prevent the cat from dislodging the urinary catheter.

The urinary catheter is usually kept in place for 1 to 2 days. It can be removed when urine appears relatively free of crystalline material (grit) and is not grossly cloudy or bloody. It should be removed in the morning on the day of discharge, and the cat monitored to make sure it can urinate before going home. If the cat cannot urinate, a urethral plug may still be present, or there may be a functional voiding problem because of urethral spasm or bladder atony. Sedation and urinary catheterization are required to determine the cause. A physical obstruction should be detected during passage of the urinary catheter; however, the urinary catheter passes relatively easily if urethral spasm is the cause.

Urethral spasm may be treated with phenoxybenzamine (2.5 to 7.5 mg/cat orally q12-24h). The onset of action is relatively slow (hours), and effectiveness increases over several days. For this reason some clinicians advocate starting phenoxybenzamine soon after initial urinary catheterization when the cat is stable and can tolerate oral drugs.

LONG-TERM MANAGEMENT

Recurrent bouts of obstructive or nonobstructive feline lower urinary tract disease are common. Long-term management has been extensively reviewed (Kruger, Osborne, and Lulich, 2000; also see Chapter 205). Most authors agree that increasing water intake is important. Water intake can be maximized by changing the diet to wet food, ensuring availability of adequate fresh water, and encouraging the cat to take in as much water as possible. Flare-ups of idiopathic cystitis may be precipitated by stress; therefore creating a stress-free environment for the cat is also beneficial. Recommendations for pharma-

cologic treatments as home management of affected cats are often supported by anecdote and little objective evidence of efficacy.

The owner should be warned about the possibility of reobstruction and advised to monitor the cat's urination carefully. The most common time for reobstruction appears to be within the first few days or week after discharge from the hospital. In my experience reobstruction is not common when cats are hospitalized and treated as described here.

If a cat has multiple obstructive episodes despite appropriate preventive medical therapy, a perineal urethrostomy can be performed to minimize obstructive complications of feline lower urinary tract disease. The owner should be warned of the potential adverse effects of perineal urethrostomy, including stricture formation or recurrent urinary tract infections. In addition, the owner should clearly understand that the procedure does not eliminate the underlying causes of lower urinary tract inflammation.

Urinary Incontinence and Micturition Disorders: Pharmacologic Management

INDIA F. LANE, *Knoxville, Tennessee*
JODI L. WESTROPP, *Davis, California*

Although the primary pharmacologic agents useful in the management of micturition disorders have not changed in the past decade, the availability of many compounds has varied. Alternative products often are sought during times of reduced availability and when first-line treatment choices fail. In this chapter we present a brief review of the rationale for pharmacologic manipulation of micturition and updates on available agents and new approaches. Drug information and dosing recommendations can be found in Tables 207-1 and 207-2.

PHARMACOLOGIC MANAGEMENT OF URINARY RETENTION

To enhance urine voiding, pharmacologic agents are chosen to improve urinary bladder contractile function, relax urethral outlet resistance, or both. In most instances the urethral outlet resistance is manipulated first, with bladder function assessed and treated after urethral resistance declines.

Urethral outlet resistance is maintained by smooth and striated muscle components of the urethra, as well as physical features of the urethra that aid closure (urethral folds, moist epithelial seal, urethral length and position). Manipulation of urethral resistance has relied on manipulation of the muscular components, primarily smooth muscle. In general, smooth muscle relaxation is effective in many dogs with functional urinary obstruction, in some dogs and cats with neurogenic disorders of micturition (e.g., postintravertebral disk disease [IVDD]), and for relaxing the urethral outlet during bethanechol administration. Agents directed at smooth muscle are only partially effective for cats with urethrosppasm when striated muscle contraction predominates. Similarly they are less effective for detrusor-striated urethral muscle dyssynergia associated with neurogenic disorders and for some cases of idiopathic dyssynergia. Because it is clinically difficult to discern the relative influence of smooth or striated muscle in voiding dysfunction, smooth muscle relaxants are often administered first, with striated muscle relaxants added if necessary.

Activation of terminal α -adrenergic receptors elicits contraction of smooth muscle in the urinary bladder neck and urethra; selective or nonselective antagonism of these receptors can be achieved pharmacologically. The nonselective

agent phenoxybenzamine is reasonably effective in dogs. The agent may not be available in some countries, and pricing has been variable. Prazosin has been a useful, potent, and inexpensive alternative in dogs and cats, although the drug must be compounded for accurate administration in small dogs and cats. Prazosin is usually effective when given once or twice daily; some earlier texts recommended more frequent administration. Hypotension and sedation are the most common and worrisome adverse effects of α -antagonists. Uroselective α_1 -antagonists (terazosin, doxazosin, tamsulosin) are readily available for human use and are most commonly used to modulate prostatic and urethral smooth muscle in men with prostatic hypertrophy. No studies evaluating these drugs in dogs are available. Phenothiazine derivatives (e.g., acepromazine) antagonize α -receptors and can be highly effective urethral relaxants in stable, normotensive patients. Sedation may be an unwanted adverse effect.

Striated muscle relaxation is most commonly obtained using benzodiazepines such as diazepam or alprazolam. Sedative effects limit the long-term use of these agents for urologic disorders. Oral diazepam has a very short half-life; and, if this drug is administered for urethral relaxation, it should be given 15 to 30 minutes before taking the pet outdoors to void. Dantrolene, baclofen, and cyclobenzaprine have also been recommended as striated muscle relaxants for small animals, but their use has been limited by side effects.

The effect of α -antagonists on voiding is appreciated relatively quickly, but full effect may take several days. If urinary bladder function is weak, other agents can be administered to improve bladder contraction. Urinary bladder contraction is enhanced by activating the terminal receptors for parasympathetic input or antagonizing the (sympathetic) adrenergic input on β -receptors in detrusor muscle. Bethanechol, a parasympathomimetic agent, remains the primary treatment for detrusor atony or dysfunction, although the efficacy of orally administered bethanechol is questionable. Cholinesterase inhibitors (neostigmine, pyridostigmine) have been used to increase parasympathetic activity when bethanechol is unavailable. Other drugs that stimulate urinary bladder contraction include the prokinetic agent cisapride and β -blocking agents such as propranolol. When pharmacologic intervention for bladder evacuation is unsuccessful,

Table 207-1

Pharmacologic Agents Useful in the Management of Urine Retention

Category/Agent	Mechanism	Recommended Dosage	Possible Adverse Effects	Contraindications or Comments
Agents That Facilitate Urethral Relaxation				
Acepromazine	Skeletal muscle relaxation via neuroleptic effect; smooth muscle relaxation via α -antagonism	Up to 0.1 mg/kg IV q12-24h (doses as low as 0.02 mg/kg IV may be effective) 1.1-2.2 mg/kg PO q12-24h Cat: 0.125-0.25 mg/cat PO q12h	Hypotension Sedation Disinhibition	Hypovolemia Cardiac disease Seizure disorder
Alprazolam	Centrally acting anxiolytic benzodiazepine		As for diazepam, except that idiopathic hepatic necrosis has not been documented.	May be a good alternative to diazepam if oral therapy is needed
Baclofen	Skeletal muscle relaxation	Dog: 1-2 mg/kg PO q8h Cat: not recommended	Weakness GI upset Pruritus	
Dantrolene	Skeletal muscle relaxation via direct effects	Dog: 1-5 mg/kg PO q8-12h Cat: 0.5-2 mg/kg PO q8h 1 mg/kg IV	Weakness Sedation GI upset Hepatotoxicity	Cardiac disease
Diazepam	Skeletal muscle relaxation via central effects (benzodiazepine)	Dog: 2-10 mg/dog PO q8h Cat: 1-2.5 mg/cat PO q8h or prn	Sedation Paradoxical excitation Idiopathic hepatic necrosis (with PO use in cats only) Polyphagia	Pregnancy Hepatic disease
Phenoxybenzamine	Smooth muscle relaxation via nonspecific α -antagonism	Dog: 0.25 mg/kg PO q8-12h or 2.5-20 mg/dog PO q8-12h Cat: 1.25-7.5 mg/cat PO q8-12h	Hypotension Tachycardia GI upset	Cardiac disease Hypovolemia Glaucoma Renal failure Diabetes mellitus (type II)
Prazosin	Smooth muscle relaxation via α -1 antagonism	Dog: 1 mg/15 kg PO q8-12h Cat: 0.25-0.5 mg/cat PO q12-24h	Hypotension Mild sedation Ptyalism	Cardiac disease Renal failure
Terazosin	Smooth muscle relaxation via α -1 antagonism	Dog: 0.5-5 mg/dog q12-24h Cat: not determined	Hypotension Mild sedation Ptyalism	Cardiac disease Renal failure
Tamsulosin*	Uroselective relaxation via α -1 antagonism	Dog: 0.1 mg/10 kg q24h	Hypotension	Empiric dosage
Agents that Facilitate Urinary Bladder Contractility				
Bethanechol	Parasympathomimetic	Dogs: 5-25 mg PO q8h Cats: 1.25-5 mg PO q8h	Ptyalism Vomiting Diarrhea	Outlet obstruction or high outlet resistance GI obstruction Atropine is antidotal
Cisapride	Prokinetic; may enhance acetylcholine release	Dogs 0.5 mg/kg PO q8h Cats: 1.25-5 mg/cat PO q8-12h	Diarrhea Possible abdominal pain	GI obstruction Reduce dose with hepatic insufficiency

Modified from Fischer JR, Lane IF: Incontinence and urine retention, BSAVA Manual of canine and feline urology, ed 2, Gloucester, England, 2007, pp 26-40.

GI, Gastrointestinal; IV, intravenously; PO, orally; prn, as needed.

*Dosage and safety of this drug are not determined. Contraindicated in cats.

urine removal via multiple catheterizations or placement of a tube cystotomy is warranted.

PHARMACOLOGIC MANAGEMENT OF URINARY INCONTINENCE

Manipulations to improve urine storage include those aimed at increasing urethral outlet resistance or increasing urinary bladder accommodation and storage func-

tion. Because urethral incompetence (urethral or primary sphincter mechanism incompetence) is the most common micturition disorder in dogs, the most common treatments include reproductive hormones and α -agonists. Other agents have indirect effects on urethral function or combined effects on the urinary bladder and urethra.

Reproductive hormones are reasonably effective in improving continence in dogs with urinary incontinence. Estrogens such as diethylstilbestrol (DES), stilbestrol,

Table 207-2

Pharmacologic Agents Useful in the Management of Urinary Incontinence

Agent	Classification	Recommended Dosage	Possible Adverse Effects	Contraindications or Comments
Diethylstilbestrol (DES) Stilbestrol	Reproductive hormone	Dogs: 0.1-1 mg/dog PO q24h for 5-7 days, then weekly or as needed	Estrus Behavior change Myelosuppression Pyometra in intact female	Males Cats Pregnancy
Stilbestrol (alternate regimen)	Reproductive hormone	Dogs: 0.04-0.06 mg/dog PO q24h for 7 days, reduced weekly to 0.01-0.02 mg/dog/day	As with DES	As with DES
Premarin	Conjugated estrogen	Dogs: 0.02 mg/kg PO q24h for 5-7 days, then q2-4days or as needed	As with DES	As with DES
Estriol	Reproductive hormone	Dogs: 0.5-1 mg/dog PO q24h for 5-7 days, then q2-3days as needed	As with DES	As with DES
Estriol (alternate regimen)	Reproductive hormone	Dogs: 2 mg/dog PO q24h for 7 days; then reduce daily dose by 0.5 mg each week to establish minimal effective daily dose; then try every other day administration	As with DES Adverse effects more common at higher doses	As with DES
Testosterone cypionate	Reproductive hormone	Dogs: 2.2 mg/kg IM q4-8weeks	Behavior change Perianal adenoma perineal hernias, prostatic disorders Aggression	Cardiac, renal or hepatic disease
Testosterone propionate	Reproductive hormone	Dogs: 2.2 mg/kg IM q2-3days	As for testosterone cypionate	As for testosterone cypionate
Phenylpropanolamine (PPA)	Indirect α -agonist	Dogs: 1.5 mg/kg PO q8-12h or 12.5-75 mg PO q8-12h	Anxiety Aggression Anorexia Hypertension Tachycardia	Some cardiac disease Hypertension \pm anxiety disorders
Ephedrine Pseudoephedrine	α -Agonist α -Agonist	Dogs: 1.2 mg/kg PO q8h Dogs: 0.2-0.4 mg/kg (practically, 15-60 mg total dose per dog) PO q8-12h	As with PPA As with PPA	As with PPA As with PPA
Imipramine	Antimuscarinic, α/β -agonist	Dogs: 5-15 mg PO q12h	Sedation Dry mouth Urinary retention GI upset	Seizure disorders Use of other anticholinergic or CNS depressants, glaucoma, GI obstruction, renal or hepatic disease, cardiac arrhythmias
Oxybutynin	Antimuscarinic	Cats and small dogs: 0.5-1.25 mg total per dose Larger dogs: 2.5-3.75 mg total per dose	As for imipramine	Glaucoma, GI obstruction, renal or hepatic disease, cardiac arrhythmias, hypertension
Dicyclomine	Antimuscarinic	Dogs: 5-10 mg/dog PO q8h	As for imipramine	As for oxybutynin
Depot leuprolide	GnRH analog	Dogs: 11.25 mg/dog		May be redosed as needed May be used in combination with α -agonists
Depot deslorelin	GnRH analog	Dogs: 5-10 mg/dog		May be redosed as needed As for leuprolide

Modified from Fischer JR, Lane IF: Incontinence and urine retention, BSAVA Manual of canine and feline urology, ed 2, Gloucester, England, 2007, pp 26-40.
CNS, Central nervous system; GI, gastrointestinal; GnRH, gonadotropin-releasing hormone; IM, intramuscularly; IV, intravenously; PO, orally; prn, as needed.

estriol, and conjugated estrogens (Premarin) improve urethral resistance by increasing α -adrenergic receptor responsiveness and improving urethral vascularity and other mucosal epithelial characteristics. Estrogen compounds are particularly useful in spayed females. Although many estrogen products are readily available as hormone replacement treatment for women, the most reliable veterinary product, DES, is no longer commercially available because of human health risks associated with the drug. DES is available from many veterinary compounding agencies; reliability depends on the source. The effectiveness of most estrogen treatments is improved by using a "loading" dose regimen followed by a frequency of administration tailored to the individual patient and drug (see Table 207-1). Estrogens can also be used concurrently with phenylpropanolamine (PPA) and are theorized to be synergistic when combined therapy is used. Estrogens are often chosen for dogs that do not tolerate α -agonists, those that are not completely continent on α -agonists alone, and for clients who prefer the intermittent treatment regimen. Some dogs treated with commercially available estrogen products require more frequent administration than with DES.

Estrogen treatment improves continence in 60% to 80% of treated dogs; in a recent open-label trial of estriol, veterinarians reported continence in 61% of 129 dogs and improvement in an additional 22%; owner-reported responses were slightly less favorable (Mandigers and Nell, 2001). A prolonged residual effect of estrogen administration can be seen in some dogs after a period of successful treatment. Administration can be stopped on a trial basis and restarted when incontinence returns (usually weeks to months).

Possible adverse effects of estrogens include signs of estrus, hair loss, behavioral changes, and bone marrow suppression. Estrogenic side effects are most common during the loading dose of estriol and with higher doses of DES. Bone marrow suppression is unlikely in dogs treated with appropriate doses of the drugs listed here, but owners should be advised of this potentially fatal adverse effect. Estradiol cypionate (ECP), a repository preparation, should never be used for urinary incontinence in dogs because of the higher risk of bone marrow suppression. Estrogen administration should be avoided in male dogs and in dogs with a history or breed predilection for immune-mediated disease, since estrogens are immunostimulatory. Estrogens are not very effective and poorly tolerated in cats.

Another reproductive hormone treatment using gonadotropin-releasing hormone (GnRH) analogs has recently been applied to the treatment of urinary incontinence. Reichler and associates (2003) reported their experience with leuprolide, buserelin, and deslorelin, GnRH analogs that suppress sex hormone release. In theory, chronically unsuppressed follicle-stimulating hormone (FSH) and luteinizing hormone (LH) release (because of lack of negative feedback) in ovariectomized dogs may contribute to urinary incontinence. Administration of GnRH analogs paradoxically results in reduced FSH and LH over time. In Reichler's series the drugs appeared useful in 12 of 13 dogs with refractory incontinence, either alone or in combination with

α -agonists. In a more recent trial 9 of 23 incontinent dogs treated with long-acting leuprolide were continent for prolonged periods (70 to 575 days); another 10 of the dogs had partial response. However, these 23 dogs also responded to phenylpropanolamine, with 92% overall reduction in urine leakage. There were no apparent adverse effects of GnRH treatment reported in this study, but long-term use of these drugs in dogs has not been evaluated. GnRH analog administration may prove to be a valuable long-acting treatment that would alleviate the need for daily or weekly medication; however, availability of GnRH analogs is limited in the United States.

Sympathomimetic drugs with α -agonist effects, including phenylpropanolamine, phenylephrine, and pseudoephedrine, have been extremely effective in improving or controlling urinary incontinence. Like DES, phenylpropanolamine has been removed from commercial production for humans but is produced under a Food and Drug Administration-compassionate use provision by veterinary compounding pharmacies. Over-the-counter (OTC) pseudoephedrine products are now semicontrolled by pharmacies to limit availability of the compound for methamphetamine production. In many states products containing pseudoephedrine in tabular form must be requested from the pharmacist and signed for by the consumer. Many products have been replaced with phenylephrine at this time. Although phenylpropanolamine has been studied most often, all α -agonists have the same mechanism of action and approximate dose range for the treatment of urethral incompetence. OTC products containing antihistamines or acetaminophen should be avoided. Tolerability and severity of side effects, including restlessness, tachycardia, systemic hypertension, anorexia, gastrointestinal side effects, and aggression and other behavioral changes, may vary among products. For an individual dog the treatment response also may vary among drugs and among formulations of the same drug (e.g., regular versus time-released products).

Although most dogs usually will become continent or improve dramatically with either estrogen or α -agonist administration, the two drugs can also be combined for synergistic effect in the same patient. Combination treatment allows estrogen to "prime" the urethral receptors for α -agonist treatment. Starting doses are the same as for each drug when used individually, but the dose of both products often can be reduced slightly over time if the combination is effective.

Other pharmacologic agents that may be useful in unusual or refractory cases include anticholinergic (antimuscarinic) agents that enhance bladder storage or agents that act on both urinary bladder and urethral smooth muscle to improve storage (imipramine, duloxetine), but these drugs have not been evaluated in clinically affected dogs. Anticholinergic agents are quite effective for detrusor instability (overactive bladder or urge incontinence) in which involuntary detrusor contractions occur and cause inappropriate leakage of urine. True detrusor instability is rare in animals, but these agents can be helpful in improving urine storage in select animals, either alone or in combination with α -agonists or reproductive hormones. Without urodynamic documentation of poor

bladder storage function or detrusor instability, trial treatment can be considered in animals in which urge incontinence appears likely. These dogs or cats usually leak urine when active (i.e., when walking, jumping, or moving); urine dribbling may appear behavioral. Oxybutynin is the most commonly recommended anticholinergic agent. The authors have limited experience using the new anticholinergic tolterodine (Detrol, Pharmacia and Upjohn). Other agents, including amitriptyline, imipramine, flavoxate, and dicyclomine, also have anticholinergic effects. Imipramine and amitriptyline, tricyclic antidepressants, may improve urine storage by several mechanisms, including anticholinergic, α -adrenergic and β -adrenergic effects. However, imipramine has not proven very effective in clinical application. Side effects of antimuscarinic agents include dry mouth, blurred vision, urine retention, and gastrointestinal upset; they significantly limit tolerance of the drugs in humans but appear well tolerated by dogs. Ptyalism and gastrointestinal symptoms are possible in dogs and usually are remedied by reducing the dose. Clients may be familiar with the heavily marketed product tolterodine for overactive bladder in humans. This antimuscarinic agent is touted for once-daily administration and reduced side effects when compared to other available agents. There are no published reports of the use of the drug in small animals at this time.

Duloxetine, a serotonin and norepinephrine reuptake inhibitor, may improve urethral striated muscle resistance and bladder capacity and has proven useful in women with stress incontinence. The most common adverse effect in women was nausea, which can be minimized by slow dose escalation (Norton et al., 2002; Oelke, Roovers, and Michel, 2006). Experience is limited in small animals at this time.

Other diagnostic considerations and management recommendations for patients with refractory micturition disorders can be found in the references (Lane, 2003; Fisher and Lane, 2003). Endosurgical approaches to urinary obstruction and urinary incontinence are described in other chapters in this volume (see Chapters 208 and 209).

Urinary Incontinence: Treatment With Injectable Bulking Agents

JULIE K. BYRON, *Urbana, Illinois*

DENNIS J. CHEW, *Columbus, Ohio*

MARY A. McLOUGHLIN, *Columbus, Ohio*

Few problems in small animal practice are as frustrating to the owner and veterinarian as urinary incontinence. Although not life threatening, urinary incontinence is unacceptable to most pet owners. Affected dogs that cannot be managed successfully often are euthanized, surrendered to a humane shelter, or kept permanently outdoors. A search of records submitted to the Veterinary Medical Database revealed that 0.5% of dogs seen at veterinary teaching hospitals from 1994 to 2003 were diagnosed with urinary incontinence (VMDB, 2005).

The causes and manifestations of urinary incontinence vary; thus accurate diagnosis and elucidation of the underlying etiology is essential for therapeutic success. However, even for patients in which the disease is localized to urethral sphincter mechanism incompetence (USMI), complete continence with medical treatment is not guaranteed (see Chapter 207). Recently use of injectable bulking agents has been increasing in treating dogs that fail medical therapy. This approach, adopted from human therapeutics, shows promise in both reducing the need for medical therapy and improving response to it.

ETIOLOGY

Maintenance of urinary continence relies on many factors. Normally the major component of urethral tone is comprised of smooth muscle. Mucosal integrity, vasculature, and connective tissue surrounding the urethra also play important roles in preserving continence. In addition, healthy urothelium, surface tension from glandular secretions, and the pliability of the mucosa contribute significantly to coaptation of the urethral walls.

Bladder position and the exposure of the vesicourethral junction and proximal urethra to intraabdominal pressure also are important in preserving continence. When sudden increases in abdominal pressure occur, an increase in pressure occurs both within the bladder and in the proximal and midurethra, termed *pressure transmission* (Gregory and Holt, 1994). Several studies have evaluated the relationship of urethral position and length, as well as the vesicourethral angle to incontinence (Gregory, 1994; Gregory et al., 1996). However there is a large amount of overlap in these measurements between normal and affected dogs; many incontinent dogs have been found to have short urethras and intrapelvic bladders. Despite lack of definitive evidence for a direct cause-and-effect

relationship, bladder and urethral position appear to be an important risk factor for incontinence.

The relationship of hormone status to incontinence has long been recognized. As many as 20% of neutered female dogs are expected to develop some degree of urinary incontinence during their lives, and 75% of these dogs will do so within 3 years of neutering. Decreased estrogen concentrations in women are associated with loss of urethral muscle tone, urethral vascular atrophy, and decreased glandular secretions, affecting major components of the continence mechanism. Decreased estrogen concentrations are likely a factor in the development of incontinence in dogs, but the lack of clinically recognized incontinence in anestrus-intact females (and the many ovariectomized dogs without incontinence) supports a more complex mechanism than a simple lack of trophic effect (Richter and Ling, 1985). Recent evidence suggests that increases in luteinizing hormone and follicle-stimulating hormone associated with estrogen decrease also may play a role in the development of incontinence in dogs, but the mechanism has yet to be determined (Reichler et al., 2005).

Other risk factors for incontinence are breed, body weight, and tail docking. Among the breeds found to be at increased risk for urinary incontinence are Old English sheepdogs, Doberman pinschers, German shepherd dogs, boxers, weimeraners, rottweilers, and Irish setters. Interestingly, of the breeds evaluated, Labrador retrievers appeared to have a decreased risk of incontinence, particularly among large-breed dogs (Holt and Thrusfield, 1993). Large- and giant-breed dogs and dogs weighing over 20 kg have been found to have a significantly increased risk of developing incontinence, whereas small-breed dogs have decreased risk. Tail docking has been suspected to be a contributor to the onset of incontinence in dogs because damage to the muscles of the pelvic floor is considered to be a contributing factor in the development of stress incontinence in women, but no studies have directly related tail docking to incontinence. However, tail docking is common; and among the breeds with increased risk of incontinence many females are docked as neonates but develop the disorder only after they are neutered, sometimes as older adults.

Although the risk factors remain unclear, the most common type of urinary incontinence recognized in female dogs is USMI. Incontinent female dogs have been found to have lower urethral closure pressures than continent

dogs, and closure pressure increases in patients successfully managed with medical therapy. As noted previously, the closure pressure of the urethra depends on multiple factors; however, α -adrenergic receptor number and stimulation have been identified as primary therapeutic targets.

DIAGNOSIS

History and Minimum Database

The International Continence Society defines incontinence as “the complaint of any involuntary leakage of urine.” There are several underlying reasons for the client complaint of “leaking urine,” including behavioral, endocrine, and infectious causes, as well as USMI. The most important point to establish with owners is the involuntary nature of the problem. Many owners perceive submissive urination, pollakiuria, or polyuria as incontinence. For this reason the owner needs to be questioned extensively to establish the diagnosis. Water and food intake; general health; medical treatments; and appearance, frequency, and volume of urine voiding are all factors that should be discussed. It is essential to the diagnosis that the dog seem unaware of the leakage at the time it occurs, although it may “clean up” afterwards or lick the vulvar area frequently. Irritation of the vulva can occur because of a constantly wet environment or secondary bacterial infection. In addition, although difficult to definitively diagnose without urodynamic studies, detrusor instability (overactive bladder) may play a role in some incontinent patients.

Many incontinent dogs, especially those older than 7 years of age, develop incontinence after becoming polyuric from an unrelated disease process or following diuretic therapy of heart failure. Development of incontinence can therefore signal another, more serious problem that has otherwise escaped the owner's observation. We recommend that all incontinent dogs receive a general health screen, including complete blood count, serum electrolyte and chemistry evaluation, urinalysis (collected by cystocentesis), and systolic blood pressure measurement. In addition, because pollakiuria may be misinterpreted as incontinence by some owners and because of the increased risk of urinary tract infection in incontinent dogs, a quantitative urine culture should be performed.

Urodynamic Evaluation

The term *urodynamics* refers to several tests evaluating lower urinary tract function. The rationale behind the development of this technique is the theory that to maintain continence urethral pressure must be higher than intravesical pressure during the filling and storage phases of micturition. The three most commonly performed tests are the cystometrogram (CMG), an evaluation of bladder storage and contractile function), the Valsalva leak point pressure (VLPP), and the urethral pressure profile (UPP). These tests can be used to differentiate between detrusor instability and USMI, and they can assist in establishing severity of disease. The predictive value of urodynamic results is still debated, and improved

standardization of techniques will increase its reliability and diagnostic worth. At this time no studies have been published evaluating the predictive value of the UPP or VLPP on response to periurethral bulking agents in dogs. Studies in women have had mixed results, with the complicating factor that the VLPP does not always increase in patients with real improvement in continence. Based on our experience, there does not appear to be a strong correlation between the UPP and the success of periurethral bulking agent therapy. However, this does not mean that there is no role for urodynamics in the assessment of patients for bulking agent treatment. It is important to verify the presence of USMI and any component of overactive bladder before placing bulking agents because the relative contribution of each of these disorders will guide therapeutic decisions. Many dogs may have a significant component of overactive bladder and require anticholinergic therapy in addition to bulking agents to attain continence.

TREATMENT

Treatment of urinary incontinence has taken several avenues. Pelvic floor muscle training and pharmacologic treatments are considered primary therapy in humans, but surgical procedures for stress incontinence in women have been described for over 100 years and are still applied extensively. Both medical and surgical treatments have been adapted for small animals, including sympathomimetic drugs, estrogens, periurethral injections, and colposuspension. The use of injectable bulking agents is becoming more widespread and, with the advent of newer materials, shows significant promise in treating incontinence in dogs.

Injectable Bulking Agents

Injection of bulking agents to prevent urine leakage has been reported as early as 1938, with a description of cod liver oil injection in women. Although many materials have been investigated, the theory behind all injectable bulking agents is to narrow the diameter of the urethral lumen, thus creating outflow obstruction and allowing the urethral sphincter to close more easily. In veterinary medicine injection of bulking agents has been performed in selected centers for many years but is now seeing more widespread application following the introduction of safer and more effective bulking materials.

Patient Selection

Because of cost and concerns about duration of postprocedure continence, patient selection for urethral injection is important. The ideal patient has USMI without additional active lower urinary tract disease, including urinary tract infection. Patients should be screened via the CMG and any significant degree of detrusor instability managed medically before the injection procedure. As discussed in the following paragraphs, patients with ectopic ureters may benefit from the procedure; however, the location of the ureteral stomata is important. The majority of our periurethral injection patients have previously tried and failed medical therapy. In spite of this, many of these

patients have an improved response to α -agonists after injection. Based on anecdotal data, previous response to medical therapy does not appear to predict outcome of injection therapy. Currently injection therapy is recommended most frequently to those patients with USMI and failure or declining efficacy of α -agonist or estrogen therapy.

Procedure

The bulking material is injected into the submucosa of the proximal urethra through a transurethral cystoscope or via a periurethral approach (Fig. 208-1). The periurethral approach has been found to have a slightly higher risk of early postoperative complications in women and has not been used in dogs. Using the transurethral approach, three blebs are created in the urethral wall at the 2, 6, and 10 o'clock positions, approximately 1 cm distal to the bladder neck, effectively narrowing the urethra (Figs. 208-2 and 208-3).

Following standard protocols, a cystoscope is passed into the external urethral meatus and advanced to the level of the trigone. The scope is then withdrawn to a point just caudal to the bladder neck. When the urethra and bladder are moderately infused with fluid, the demarcation between urethra and bladder at this level is relatively clear. The injection needle is passed into the instrument port and advanced submucosally with the bevel pointing toward the mucosa. The bevel of the needle is then rotated 180 degrees, and the injection is begun. The material must be injected slowly with the scope held very still because the urethral mucosa tears easily, leading to loss of the injected material and the need for reseating of the needle. Each bleb is filled with approximately 0.5 to 1 ml of material initially; however, the exact amount needed varies, depending on patient size and conformation, as well as the material injected. Some blebs may be larger than others because the more lateral portions of the wall are easier to fill. The goal is visual occlusion of the urethra; however, there is little risk of functional obstruction to voiding. If a concern about obstruction exists, a red rubber catheter gently passed into the urethra flattens the injected material and opens the urethra. Each bleb of

Fig. 208-1 Cystoscopic view of the urethra of a female dog. The needle in the foreground is the transurethral injection needle extending from the instrument channel of the scope.

Fig. 208-2 Cystoscopic view of the urethra of a female dog. The injection needle is placed through the mucosa, and glutaraldehyde cross-linked bovine (GAX) collagen is being injected under the mucosa.

material should be placed in the same plane of the urethra to improve coaptation of the urethra.

Bulking agents

The ideal injectable bulking agent is easily delivered, biocompatible, nonantigenic, noncarcinogenic, stable within tissue, and reasonably cost-effective. Over the past 70 years several different agents have been used as the injected material; however, improvement in continence was rarely achieved without significant scarring or sloughing of the urethra. Recent application of safer injectable agents, particularly collagen preparations, has improved the outcome of the procedure. Veterinary experience with collagen compounds, as well as their precursor Teflon, are summarized here.

Fig. 208-3 Cystoscopic view of the urethra of a female dog after proper placement of submucosal glutaraldehyde cross-linked bovine (GAX) collagen.

Polytetrafluoroethylene paste. Polytetrafluoroethylene (PTFE; Teflon Polytef Paste, Dupont) was the first widely used urethral bulking agent in both humans and dogs. The procedure was reported in one study to improve continence in 57% of 298 women treated with just one set of injections (Lampante, Sparwasser, and Charvalakis, 1984). Its use in women decreased after it was found that the PTFE particles migrated after just a few months from the injection site to other parts of the body, including the brain, lungs, and lymph nodes. In addition, the PTFE caused a severe inflammatory reaction at the site of injection and often was extruded, leaving ulcers in the urethral mucosa. The results of PTFE injection have been reported for 22 dogs that either had failed α -agonist treatment or for which such treatment was unsuitable (Arnold et al., 1989). In this group of dogs 36% were continent after one PTFE injection, and an additional 41% were continent after a second injection. The majority of these dogs required adjunct treatment with phenylpropanolamine (PPA) to maintain continence. Fourteen (64%) dogs relapsed after 4 to 17 months. Necropsy was performed in 3 dogs 2 to 11 months after injection; PTFE was not found at sites other than the periurethral tissues. Due to granulomatous reactions at the injection site and the development of improved injection materials, PTFE has been abandoned as a periurethral injection material in women and is currently unavailable in North America. However, PTFE is still used by some European veterinarians as a more economical alternative to cross-linked collagen, particularly in large breed dogs.

Bovine cross-linked collagen. Glutaraldehyde cross-linked bovine (GAX) collagen (Contigen Bard Collagen Implant, Bard Urological Division) today is the most widely used periurethral bulking agent in humans. Before its use in urology, collagen had been used safely by plastic surgeons and dermatologists in a variety of tissues; migration of injected collagen was not observed (Kershen, Dmochowski, and Appell, 2002). The collagen is supplied in 2.5-ml syringes and is injected using a 5-Fr transurethral injection needle (Contigen Transurethral Injection System, Bard Urological Division) placed through the instrument port of a rigid cystoscope (Figs. 208-4 and 208-5). Rather than causing an inflammatory reaction, the GAX implant is vascularized and invaded by fibroblasts. Fibroblasts lay down new endogenous collagen, stabilizing the implant. In humans no evidence of migration within the body has been found during 15 years of GAX use. The postoperative cure rates have been very good; but, as with any injectable treatment, long-term outcome is poor compared to that of other surgical procedures in women. Reported cure rates in women range from 60% to 80%, but this success decreases to 40% after 2 years (Winters et al., 2000; Kershen, Dmochowski, and Appell, 2002). In one metaanalysis of studies performed before February 2003, it was found that there were no subjective or objective benefits in the outcome when compared to surgery, but few studies were available for analysis (Pickard et al., 2003). The biggest advantage of collagen injection in humans is the low morbidity associated with this outpatient procedure. The procedure is especially useful in elderly or frail patients who cannot undergo general anesthesia and surgery. The low morbidity and minimally

Fig. 208-4 Packaging of the glutaraldehyde cross-linked bovine (GAX) collagen. (Courtesy Contigen, Bard Urological Division.)

invasive nature of collagen injection also makes this procedure attractive for the treatment of refractory incontinence in dogs. In this species surgical procedures for incontinence have not proved advantageous for either short- or long-term outcomes.

Response to Collagen Injection in Dogs

Three reports have described the outcomes of collagen injection in the incontinent female dog. The first report included 32 spayed female dogs refractory to PPA treatment and subsequently treated with periurethral collagen injection (Arnold et al., 1996). Of these dogs, 53% were continent after one or two injections without the addition of PPA. With PPA the success rate increased to 75%. No post-operative complications were observed, and six of these dogs (19%) were observed to be continent longer than 30 months after the first injection. A longer-term follow-up study was performed by the same group of investigators involving 40 dogs over 7 years (Barth et al., 2005).

Fig. 208-5 5-Fr transurethral injection needle system. (Courtesy Contigen, Bard Urological Division.)

In the larger study 68% of the dogs were continent for a mean of 17 months (range 1 to 64 months) after collagen injection. Improvement was also observed in an additional 25%, and of these 60% became continent after the addition of α -agonist therapy. Mild and transient side effects were noted in 15% of treated dogs, including stranguria, hematuria, and vaginitis. A recent retrospective study evaluated the outcome of 34 collagen injections in 29 female dogs (Byron et al., 2005). Seven of these dogs had been diagnosed with ureteral ectopia; six had received corrective surgery but had persistent postoperative incontinence. Of the treated dogs, 66% achieved complete continence immediately after the procedure, and an additional 32% were improved. Of the dogs with improved continence, 55% achieved full continence after the addition of medical therapy. The mean duration of complete continence after the procedure was 12.1 months without additional medical therapy. The majority of dogs had an improved response to medical therapy if added after continence declined. Overall client satisfaction with the procedure was 88%, with 76% of the clients being 100% satisfied with the procedure. Although little data are available, addressing the success of reinjection following decline in continence after collagen injection in dogs, studies in women have been encouraging. In our experience repeated injection of collagen, either by "enhancing" the previously placed blebs or by addition of new ones, has led to improved response and reinduction of continence. Currently we recommend reinjection in patients who do not improve after initial collagen injection or who experience a decline in continence after a period of time.

A newer use of injectable collagen is in some patients with ectopic ureters. Approximately 50% of these patients continue to have some degree of incontinence after neoureterostomy. Although technically more challenging to implant because of scarring of the urethral mucosa, periurethral injection of collagen appears to improve continence. In addition, injection of collagen distal to the ectopic stoma in patients with proximally placed ureteral ectopia may reduce incontinence without more invasive surgical intervention.

Newer agents. As mentioned previously, the ideal injectable bulking agent should be easily delivered, anatomically stable, safe, biocompatible, nonantigenic, noncarcinogenic, and inexpensive. Several agents on the horizon are nearly ideal in these respects. These include but are not limited to carbon-coated zirconium beads, autologous cartilage and fat grafts, silicone microimplants, microballoons, and acellular extracellular matrix substances (Kershen, Dmochowski, and Appell, 2002; van Kerrebroeck et al., 2003). As tissue engineering advances, more potential materials will be tested. The current limi-

tation of injection therapy is the poor long-term outcome, and this obstacle must be overcome by those working to design new injectable agents.

Interventional Radiology in Urinary Diseases

CHICK W.C. WEISSE, *Philadelphia, Pennsylvania*

ALLYSON C. BERENT, *Philadelphia, Pennsylvania*

With *interventional radiology (IR)*, contemporary imaging techniques are used to selectively access vessels and other structures to deliver materials for therapeutic purposes. These techniques are most commonly performed in veterinary medicine for occlusion of patent ductus arteriosus (Chapter 165), embolization of portosystemic shunts (Chapter 134), and placement of tracheal stents (Chapter 145). *Endosurgery* involves the use of endoscopic equipment, with or without concurrent fluoroscopy, to perform minimally invasive interventions in virtually any part of the body.

Currently the investigation and application of these techniques is expanding in veterinary medicine, particularly in applications pertaining to the urinary tract. The relatively common incidence of urinary tract obstruction neoplasia and trauma, combined with the morbidity associated with traditional surgical techniques, makes the use of less invasive procedures such as laparoscopy, endoscopy, and IR highly appealing. Such interventional procedures are already considered the standard of care in human medicine. This chapter contains a brief review of some of the interventional procedures currently performed in veterinary patients, as well as some promising future urologic applications.

ADVANTAGES

The use of IR and endosurgical techniques in veterinary patients offers a number of advantages compared to more traditional therapies. These procedures are minimally invasive and lead to reduced perioperative morbidity and mortality, shorter anesthesia times, and shorter hospital stays. The less equipment-intensive procedures can result in reduced cost as well. In addition, some techniques such as palliative stenting for malignant obstructions offer alternative treatment options for conditions that may not be amenable to standard surgical or medical approaches.

EQUIPMENT

Most of these minimally invasive procedures (performed through catheters, orifices, or small percutaneous holes) are performed in clean angiography suites; traditional sterile operating rooms are not required. Entry sites receive a standard sterile scrub; operators wear full lead gowns, lead thyroid shields, caps, gowns, and masks. The radiation exposure during conventional or C-arm fluoroscopy can be substantial; thus the operator should review

radiation safety guidelines, minimize exposure time and beam size, and maximize shielding and distance from the beam whenever possible.

For many of the more commonly performed IR procedures, a traditional fluoroscopy unit is sufficient. A C-arm fluoroscopy unit has the advantage of mobility of the image intensifier, permitting multiple tangential views without moving the patient. Occasionally ultrasonography is useful for percutaneous needle access into vessels or other structures (e.g., urinary bladder, renal pelvis).

Various flexible and rigid endoscopes are used for traditional interventional endosurgical procedures. Rigid cystoscopy is performed commonly in female animals for urethral, urinary bladder, and ureteral access. Recommended diameters range from 1.9 to 6.5 mm, depending on the size of the patient. Flexible ureteroscopes (2.5- to 2.8-mm diameter) are used for lower urinary tract access in male dogs and for ureteral access in larger animals. Rigid nephroscopes (5.3- to 7.3-mm diameter) are commonly used for percutaneous nephrolithotomy. Different types of intracorporeal lithotripters and lasers are available for these procedures such as ultrasonic lithotripters, Holmium:YAG lasers, and diode-type lasers (also see Chapter 204).

TECHNIQUES

Kidney and Ureter

Percutaneous Nephrostomy

Ureteral obstruction secondary to ureteroliths or malignancy can result in severe hydronephrosis and/or life-threatening azotemia when present bilaterally or in animals with concurrent renal insufficiency. Although some patients can be managed with supportive care until a ureterolith passes, others may require surgery (see Chapter 202). Ureterotomy or other surgical approaches can require prolonged operating time and complex microsurgical technique in these often debilitated patients. An alternative strategy is to place a nephrostomy tube to relieve obstruction and thoroughly assess the patient before prolonged ureteral surgery. Nephrostomy drainage also allows aggressive fluid support and medical management of metabolic derangements to proceed in the interim. Although nephrostomy tubes are often placed surgically, *percutaneous nephrostomies* can be performed safely and efficiently in select patients to accomplish the same goals.

Under general anesthesia the skin over the paracostal area is clipped and prepared. Percutaneous needle access to

the renal pelvis is obtained, and a contrast pyelogram is performed under fluoroscopic visualization (Fig. 209-1, A). A guidewire is placed, tract dilation is performed, a locking-loop drainage catheter is advanced over-the-wire, and the loop is formed within the renal pelvis (Figs. 209-1, B and 209-1, C). The catheter is attached to a urine collection system and secured in place with a finger-trap suture and multiple tacking sutures to the body wall (Fig. 209-1, D). The patient is recovered from anesthesia, and urine output is carefully monitored. The presence of the nephrostomy tube allows drainage of urine produced by this kidney and renal pelvic access for subsequent contrast ureterography. Serial radiographic studies can be performed to determine if the obstruction resolves sufficiently without ureteral surgery.

Ureteral Stenting

Ureteral stents are placed to divert urine from the renal pelvis into the urinary bladder. This technique can be useful in patients with ureteral obstruction and has been

performed in animals to circumvent inflammation following ureteroscopy or ureteral stone retrieval (basket retrieval or laser lithotripsy), to prevent nephrolith stone fragments from causing a ureteral obstruction following lithotripsy, and to alleviate obstructions secondary to ureteral neoplasia. In addition, the presence of the ureteral stent may create sufficient ureteral dilation to permit passage of previously obstructive ureteroliths. This technique is currently under investigation for use in veterinary patients with ureterolith-induced obstructions.

Under general anesthesia concurrent cystoscopy and fluoroscopy are used to introduce a guidewire into the ureteral opening and advance the guidewire proximally (retrograde approach). A hydrophilic catheter is advanced over-the-wire under fluoroscopic guidance, the guidewire is removed, and a retrograde contrast ureteropyelogram is performed to help identify any lesions, stones, or filling defects in the renal pelvis or ureter. A stiffened guidewire is then advanced retrograde through the catheter, which

Fig. 209-1 Lateral abdominal fluoroscopic image of a cat with bilateral hydronephrosis. **A**, An 18-gauge catheter is percutaneously placed in the renal pelvis, and a contrast pyelogram is performed. **B**, Stiffened 0.035-inch guidewire advanced into the renal pelvis. **C**, Pigtail drainage catheter within renal pelvis following removal of the guidewire. **D**, Bilateral percutaneous nephrostomy tubes.

is replaced with either an indwelling double pigtail ureteral stent (Fig. 209-2) or an exteriorized pigtail catheter (see Fig. 209-6, *F*). In an antegrade technique, percutaneous nephrostomy access is achieved as described in the previous section; and the guidewire is passed down the ureter, into the bladder, and out the urethra. A ureteral dilator is passed over-the-wire and exchanged for an indwelling ureteral stent or a nephroureteral stent.

Percutaneous Nephrolithotomy

Urinary obstruction by nephroliths or proximal ureteroliths can result in progressive renal insufficiency, intractable pyelonephritis, and hydronephrosis. Small stones may pass spontaneously into the lower urinary tract; however, other uroliths require surgery to relieve the obstruction and avoid permanent renal damage. Nephrotomies, pyelotomies, or ureterotomies can be prolonged, invasive, and complicated surgeries with significant morbidity. In human patients percutaneous nephrolithotomy is considered the standard of care for large nephroliths and proximal ureteroliths (those not amenable to extracorporeal shock-wave lithotripsy or endosurgical techniques). This minimally invasive procedure aims to minimize morbidity and preserve as much renal function as possible.

Under general anesthesia the skin over the paracostal area is clipped and prepared. A retrograde ureteropyelogram is performed using the technique described previously for ureteral stenting. Ureteral catheter access is maintained to protect the ureter from stone fragment escape down the ureter and to allow for repeat ureteropyelography if necessary. The retrograde approach may not be possible in male cats or small male dogs, in which case antegrade access is obtained via a percutaneous nephrostomy. Following percutaneous needle and wire access into the renal pelvis, serially larger dilators are advanced over-the-wire to dilate the tract sufficiently for the placement of a large nephroscope sheath (Fig. 209-3). Alternatively a balloon dilation set can be used for this purpose. The nephroscope is then placed through the access sheath, and the nephrolith or proximal ureterolith is identified and fragmented using ultrasonic or laser lithotripsy. The fragments are removed via suction, grasping-forceps, or basket-retrieval methods, with instruments directed through the instrument channel. Following urolith removal a percutaneous nephrostomy tube is left in place for approximately 2 to 3 weeks to allow for progressive closure of the access tract. If there is ureteral trauma or inflammation, a percutaneous nephroureteral stent can be placed, maintaining patency from the skin tract, into the renal pelvis, and down the ureter into the bladder.

Urinary Bladder and Urethra

Antegrade Urethral Catheterization

Urethral catheterization is typically a simple and routine procedure in veterinary patients to monitor urine output, establish urine drainage in patients that are recumbent or have mechanical/functional urethral obstructions, or ensure urethral patency following surgical procedures. Occasionally retrograde catheterization can be difficult in very small (female) patients or in feline patients with significant urethral trauma (e.g., following manipulations to relieve urethral obstruction). Antegrade urethral catheterization performed under direct fluoroscopic visualization can be performed rapidly, easily, and safely in patients in which attempts at routine retrograde catheterization have failed.

Under general anesthesia (recommended) or heavy sedation, the patient is placed in lateral recumbency, and the flank and caudal ventral abdomen are clipped and scrubbed. Cystocentesis is performed, and contrast media is injected through the cystocentesis needle to define the urinary bladder and urethra (Fig. 209-4). Under fluoroscopic guidance a guidewire is advanced antegrade into the bladder and through the urethra until exiting the penis or vulva. A urinary catheter is then advanced over-the-wire in a retrograde fashion into the urinary bladder, and the guidewire is removed. The urinary catheter is secured in place in a routine fashion.

Percutaneous Cystostomy Tubes

Cystostomy tubes are placed regularly during surgery to manage veterinary patients with urinary obstructions or to divert urine away from a traumatized urethra. Occasionally these patients are severely debilitated and metabolically unstable, such that even a short period of general anesthesia would be dangerous. A variety of cystostomy tubes and techniques are available for percutaneous placement to quickly and safely establish urine drainage and/or diversion. Locking-loop drainage catheters have been used for such purposes in veterinary patients. These tubes can be placed directly into the urinary bladder via palpation alone or with fluoroscopic or ultrasound guidance.

Urethral Stenting for Malignant Obstructions

Malignant obstruction of the urethra can cause severe dysuria and life-threatening azotemia in some patients. Transitional cell carcinoma of the urethra and/or prostate is the most common lower urinary tract neoplasia encountered in small animal patients, with greater than 80% of dogs experiencing dysuria and approximately 10% developing complete urinary tract obstruction (Norris et al., 1992; Knapp et al., 2000). Chemotherapy has been successful in slowing tumor growth, but complete cures are uncommon. When signs of obstruction occur, more aggressive therapy is indicated. Cystostomy tube place-

Urinary bladder drainage can now be performed.

ment, transurethral resection, and surgical diversion have been described but are either invasive or associated with significant morbidity (complications of manual urine drainage, frequent urination, urinary tract infection)

(Stiffler et al., 2003; Liptak et al., 2004; Fries et al., 1991; Stone et al., 1988). Placement of self-expanding metallic stents using fluoroscopic guidance through a transurethral approach can provide a fast, reliable, and safe

alternative to establish urethral patency in both males and females. We have experienced good-to-excellent palliative outcomes in greater than 75% of cases (Weisse et al., 2006). Urethral stenting may also be useful in patients with benign urethral strictures when traditional therapies have failed or when surgery is refused or not indicated.

A contrast cystourethrogram is performed, and trans-urethral retrograde or antegrade guidewire access across the malignant narrowing is obtained. Measurements of the normal urethral diameter and the length of obstruction are obtained (Fig. 209-5), and an appropriately sized self-expanding metallic urethral stent is chosen (approximately 10% to 15% greater than the normal urethral diameter and 1 cm longer than the obstruction on both the cranial and caudal ends). The stent is deployed under fluoroscopic guidance, and a repeat contrast cystourethrogram is performed to document restored urethral patency.

Additional Procedures

Additional IR techniques include novel approaches to control hemorrhage, occlude vascular malformations, or reduce tumor growth. Arterial embolization involves selective, catheter-directed delivery of particulate material (typically polyvinyl alcohol) performed under fluoroscopic guidance. Chemoembolization involves the addition of chemotherapy to the particle and contrast mixture to achieve extremely high regional concentrations of chemotherapy to enhance effectiveness and minimize systemic toxicity (Weisse et al., 2002). These therapies have been performed in veterinary medicine for urogenital neoplasia and associated hemorrhage (Weisse, 2002).

Other endosurgical procedures under investigation at the University of Pennsylvania and elsewhere include ureteral cauterization for idiopathic renal hematuria, urinary polyp removal, endosurgical repair of ectopic ureters, and endoscopic-guided collagen injection for urethral sphincter mechanism incompetence. Idiopathic renal hematuria is a rare condition in which a focal area of bleeding in the upper urinary tract results in long-term hematuria, iron deficient anemia (chronically), and the potential for clot formation resulting in ureteral colic or signs of lower urinary tract disease. Surgical nephrectomy or partial renal artery occlusion of the affected side has been considered the standard treatment, although this can result in loss of a functional kidney and significant morbidity (Mishina et al., 1997). In humans the presence of a hemangioma has been visualized via ureteroscopy, which is cauterized through the instrument port of a ureteroscope (Tawfik and Bagley, 1998). This has also been performed in a small number of dogs (Fig. 209-6) (personal communication, Larry Adams). Bladder polyps are common findings in dogs and can be associated with chronic, recurrent urinary tract infections and cystolith formation and are often misinterpreted for cystic neoplasia. Using cystoscopy and laser lithotripsy (Holmium: YAG), the polyps can be removed without surgical intervention by cauterizing the stalk. Alternatively a basket can be used trap the polypoid tissue and break the stalk

with mild tension. Ectopic ureters are a common congenital anatomic deformity in dogs. Endoscopic repair of ectopic ureters is a common procedure in humans with similar conditions and has been performed in a few dogs successfully with the use of fluoroscopy, cystoscopy, and diode laser ablation. Collagen injection via urethrosopic guidance has been performed for USMI at many institutions. This procedure is indicated if medical management has failed, is contraindicated, or not tolerated (see Chapter 208).

Breeding Management of the Bitch

GARY C.W. ENGLAND, *Nottingham, England*
MARCO RUSSO, *Naples, Italy*

In the bitch the most significant problem with the management of breeding is the large variation that occurs in the time between the onset of proestrus behavior and the timing of ovulation. In addition, there is poor correlation of the behavior of the bitch with the underlying endocrine events. It is usually a misunderstanding of these two components of the normal physiology that results in mating at a time remote from the fertilization period and a failure to achieve a pregnancy.

The aim of this chapter is to review the methods that are available for the identification of the optimal time for breeding, which include observational assessments, measurement of plasma hormone concentrations, examination of exfoliated vaginal cells, vaginal endoscopy, and ovarian ultrasonography.

Unlike other domestic species, which are polyestrus, a nonpregnant bitch undergoes a 65-day luteal phase followed by a 5- to 6-month period of anestrus. The monoestrus nature of the bitch and the extended time until the return of estrus highlights for the breeder the importance of determining the timing of the period of greatest fertility.

REPRODUCTIVE PHYSIOLOGY

The basic endocrinologic events in the bitch are not unlike those of other species in that there is a preovulatory surge of luteinizing hormone (LH) that occurs approximately 2 days before ovulation. However, at the time of ovulation oocytes are immature and cannot immediately be fertilized. Fertilization can occur only after extrusion of the first polar body and completion of the first meiotic division to form the secondary oocyte. Interestingly, oocytes remain viable within the reproductive tract for 4 to 5 days after they have become fertilizable (i.e., they do not begin to undergo degeneration until 6 to 7 days after ovulation).

When compared with other species, this relative delay in the availability of oocytes for fertilization combined with their lengthened survival time has a significant impact on the onset and duration of the fertilization period of this species.

The Fertilization Period

For all species the fertilization period is the time when oocytes are available to be fertilized. In the bitch this period commences 2 days after ovulation and extends

until approximately 5 days after ovulation (Fig. 210-1). The fertilization period is likely to be the approximate time of maximal fertility, which subsequently declines rapidly over the next few days because of degeneration of the oocytes and closure of the cervix, which prevents sperm from entering the reproductive tract.

Although the fertilization period is extremely important in the bitch, it is not the only period of time during which a breeding can result in pregnancy. Intrauterine insemination after the end of the classically defined fertilization period has resulted in pregnancies of a small litter size (presumably by fertilization of aging oocytes), whereas breeding before the fertilization period commonly results in pregnancy (by virtue of sperm survival in the female reproductive tract).

The Fertile Period

The fertile period is the time during which a breeding could result in a conception. Therefore it includes the fertilization period, but it also precedes the fertilization period by several days because sperm can survive within the female reproductive tract (see Fig. 210-1). Sperm survival within the bitch means that a breeding before the fertilization period can result in a pregnancy. Interestingly, in fertile stud dogs sperm survival for up to 7 days does not appear to be uncommon, thus enabling the fertile period to commence 5 days before ovulation (i.e., sperm surviving for 7 days fertilize oocytes 2 days after ovulation).

Clearly not every stud dog produces sperm able to survive such a protracted period of time within the female reproductive tract. Dogs with poor semen quality generally have reduced sperm survival, and this accounts largely for the poor fertility seen in these individuals. Sperm that have been preserved also have a short survival time within the female reproductive tract. Therefore the potential fertile period is a feature of male fertility combined with female physiology.

THE OPTIMAL TIME FOR BREEDING

The period of peak fertility for natural breedings with fertile animals ranges from the day of until 4 days after ovulation (Table 210-1). There does not appear to be a difference in litter size when bitches are mated on any one of these days. Breedings earlier or later commonly result in lower pregnancy rates and smaller litters. In general it is thought that peak fertility commences before the true

Fig. 210-1 Schematic relationship among the fertilization period, fertile period, ovulation, and the luteinizing hormone surge.

fertilization period since sperm are required to mature within the female reproductive tract and this process of capacitation may take approximately 6 hours or more.

For the accurate prediction of the optimal time to breed, the most sensible option clearly is detection either of the LH surge or of ovulation itself. However, documentation of these events can be difficult.

Observational Assessments

Although in other species there are reasonable relationships between the time of ovulation and several aspects of the reproductive cycle, in the bitch this may not be the case. Both the time of ovulation in relation to the onset of proestrus and the behavioral characteristics typical of estrus have a poor relation with the fertilization period.

The Number of Days From the Onset of Proestrus

Many breeders rely on counting the number of days from the onset of proestrus and believe that bitches always

ovulate a defined number of days from the onset of this event. This is not the case for any breed (Fig. 210-2). The duration of proestrus is variable among bitches; and, although the “average bitch” may ovulate 12 days after the onset of proestrus, some bitches ovulate as early as day 5, and others as late as day 30 after the onset of proestrus.

The large variation in the time of ovulation (and therefore the fertilization period) explains most of the infertility that arises when bitches are bred on the 12th and 14th day, which is common breeding practice. Furthermore, it is clear that the events of one estrus are not necessarily the same at the subsequent cycle; some bitches may vary in the day of ovulation by as much as 12 days from one cycle to the next (e.g., they ovulate on day 12 of one cycle and on day 24 of the next cycle).

The Onset of Estrus Behavior

In some species the onset of the behavioral signs of estrus (acceptance of mating) can be used to determine the optimal time for breeding. However, in the bitch there is often a poor correlation between endocrine events and behavioral events. Studies on laboratory-kept bitches suggested that the onset of standing estrus occurred on average at approximately the same time as the LH surge. Using these data, 3 or 4 days after the onset of standing estrus would be a suitable time for mating. However, in many other bitches the behavioral responses correlate poorly with the underlying hormonal events. This may be because bitches are housed away from the male and introduced only when the breeder considers that the time is correct, thus inhibiting natural courtship responses; or it may simply represent greater variation than was originally thought. A further complication is that in some bitches the behavioral changes may be displayed poorly and therefore the onset of estrus may be indistinct.

It may be that, with regular examination using a standard stimulation (e.g., possibly with the use of a teaser male), the value of assessing estrous behavior could be improved. However, male dogs have been shown to

Table 210-1

Timing of Events in Relation to the Luteinizing Hormone Surge and Ovulation in the Bitch

Event	Days From Luteinizing Hormone Surge	Days From Ovulation
Period of potential fertility: the fertile period	3 days before LH surge until 7 days after LH surge	5 days before ovulation until 5 days after ovulation
Approximate time of oocyte maturation	4 or 5 days after LH surge	2 or 3 days after ovulation
Period of actual fertility: the fertilization period	4 days after LH surge until 7 days after LH surge	2 days after ovulation until 5 days after ovulation
Period of peak fertility	2 days after LH surge until 6 days after LH surge	The day of ovulation until 4 days after ovulation
Preferred breeding time using natural service or fresh semen insemination	2 days after LH surge until 6 days after LH surge	The day of ovulation until 4 days after ovulation
Preferred breeding time for males with poor quality semen or frozen-thawed semen insemination	4 days after LH surge until 6 days after LH surge	2 days after ovulation until 4 days after ovulation

Modified from England and Concannon, 2002.

LH, Luteinizing hormone.

Fig. 210-2 The relationship between day of ovulation and the onset of proestrus for normal fertile bitches.

demonstrate clear preferences for some females over others, thus making the interpretation of this criterion very difficult to assess.

When relying solely on the receptivity of the bitch, breeding should be planned shortly after the onset of estrus and should continue throughout the period of female receptivity.

The Onset of Vulval Softening

One observational assessment that may be useful in establishing the optimal time for breeding is the change in the tone of the vulva. During proestrus the reproductive tract becomes edematous, and the vulva and perineal tissues become enlarged. In proestrus there is increasing turgidity of the vulva in response to increasing concentrations of estrogen. At the time of the LH surge there is a decline in estrogen concentration combined with a concomitant rise in progesterone. This results in a reduction in edema with a consequent distinct softening of the vulva. Subjective examination of the vulva once or twice daily by gentle palpation easily demonstrates when this event has occurred. Ovulation generally occurs 2 days later; therefore breeding should commence 3 days after this event has been observed.

In cases in which only observational assessments are available for the determination of the optimum time for breeding, a combination of the onset of standing estrus and the timing of vulval softening may be used. Each of these events occurs on average 1 or 2 days before ovulation. Therefore breeding should be planned commencing 2 or 3 days later for natural mating or fresh semen insemination. These assessments are not accurate enough for use with insemination of preserved semen, which frequently has a short longevity within the female reproductive tract.

Measurement of Plasma or Serum Hormone Concentration

There is a significant surge in LH concentration approximately 2 days before ovulation in the bitch; therefore

detection of this event could be used to predict ovulation. However, there is a further preovulatory event: the luteinization of the follicle wall before ovulation (Fig. 210-3). This preovulatory luteinization results in a significant increase in plasma (serum) concentrations of progesterone before ovulation, which can be detected by conventional assay methods.

Measurement of Plasma or Serum Luteinizing Hormone Concentration

The detection of a significant increase in plasma LH concentration is a reliable and accurate method for determining the time of ovulation and therefore the optimal time to breed. In most countries there is no readily available commercial assay for canine LH, and measurement relies on radioimmunoassay techniques. As a result, this method is not used frequently since radioimmunoassays are commonly expensive and result in a delay in obtaining

Fig. 210-3 Schematic relationship among ovulation, the luteinizing hormone surge, and plasma progesterone concentration.

the results because samples are assayed in batches. A further potential problem is the requirement to take regular (daily) blood samples since the duration of the LH surge is relatively short. Recently however, an enzyme-linked immunosorbent assay (ELISA) has been marketed for the measurement of canine LH in the practice laboratory. The method is simple and rapid and has been used successfully, although it has not yet been subjected to wide investigation.

When using these methods to detect the LH surge, breeding should commence 3 or 4 days after the surge has been identified since this coincides with the onset of the fertilization period.

Measurement of Plasma or Serum Progesterone Concentration

Luteinization of the follicle wall before ovulation results in plasma progesterone concentrations beginning to increase rapidly from baseline approximately 2 days before ovulation during the LH surge. This distinct increase can be detected by serial monitoring, which allows for the anticipation of ovulation. A further increase in progesterone concentration allows confirmation of ovulation and detection of the onset of the fertilization period. Since the initial rise in progesterone is progressive, it is only necessary to collect blood samples every second or third day, unlike the daily requirement for sampling to detect the LH surge. However, when the sampling interval is increased, the accuracy of detecting ovulation is decreased. Therefore, when there is poor-quality semen, it is often prudent to perform daily estimations close to the anticipated time of ovulation.

Progesterone concentrations may be measured by radioimmunoassay, quantitative or qualitative ELISA, or immunochemilluminesce assay. Many veterinary diagnostic laboratories offer measurement of progesterone with reporting of results the same day. Several qualitative or semiquantitative progesterone ELISA test kits have become available commercially for use in the veterinary practice. Results are usually obtainable within 45 to 60 minutes of sample collection.

In general it is considered that progesterone concentrations exceed 2 ng/ml (6.5 nmol/L) on the day after the LH surge; therefore breeding can be planned in relation to this event (i.e., 4 to 6 days later). Some reports suggest that breeding should commence 1 day after progesterone concentrations exceed 8 to 10 ng/ml (25 to 32 nmol/L), which are typically seen at the beginning of the fertilization period. There are little data to link absolute progesterone concentrations with the timing of the end of the fertilization period, and this is best detected using vaginal cytology (see later paragraphs).

Examination of the Caudal Reproductive Tract

Both estrogen and progesterone have significant effects on the female reproductive tract. Although evaluation of changes within the uterine tubes and uterus is not possible, it is relatively simple to monitor changes of the vaginal wall that are induced by fluctuations in hormonal

concentration, thereby indirectly monitoring changes in these hormones.

Exfoliative Vaginal Cytology

Collection, staining, and microscopic examination of exfoliated vaginal cells is a simple method for monitoring the stage of the estrous cycle, especially when examination is performed serially. The increase in plasma estrogen during proestrus and estrus causes thickening of the vaginal wall predominantly via an increase in the number of cell layers, probably as a mechanism to protect the otherwise delicate mucosa at the time of mating. The mucosa changes from a cuboidal epithelium (in anestrus) through a transitional phase (during proestrus) into a stratified, keratinized squamous epithelium (during the fertile period). After the end of the fertilization period, as progesterone concentrations increase there is rapid sloughing of the newly developed epithelium and an uncovering of a simple cuboidal epithelium similar to that observed during anestrus.

Vaginal cells may be collected by aspiration of the vaginal cavity using a plastic catheter or by using a saline-moistened cotton swab gently rolled over the surface of the vaginal mucosa. When using the latter method, it is important not to allow contact of the swab with the vestibule or skin since collection of these cells can give erroneous results. Swabs should be introduced and removed using a small speculum or guard.

Once collected, cells should be placed onto a glass microscope slide by lightly rolling the cotton swab or by application of the aspirated fluid, which is then spread into a thin film. Smears can be stained using either a simple Wright-Giemsa stain or a modified trichrome stain. The former is readily available and has the advantage that sample preparation may take only minutes; the latter has the advantage of identification of keratinized cells, but the staining technique is laborious.

During proestrus, as plasma estrogen concentrations increase, the surface epithelial cells alter in their shape, size, and staining character. They change from small, circular cells with little cytoplasm (parabasal cells) to larger, irregularly shaped, flat (squamous) nucleated cells (intermediate cells). Ultimately they become anuclear cornified squamous cells (superficial cells) and are characterized as having no nucleus or a faint and/or small pycnotic nuclear remnant. After the end of the fertilization period during sloughing of the epithelium, the superficial cells disappear, and small parabasal cells reappear in the vaginal smear.

Polymorphonuclear leukocytes generally are present in small numbers in the anestrus vaginal smear but disappear from the smear during the fertile period because the thickened mucosa is a barrier to their migration to the surface. These polymorphonuclear leukocyte cells reappear, often in large numbers, at the end of the fertilization period as epithelial sloughing results in a thinner mucosa at the same time as there is a significant chemottractant effect within the vaginal lumen.

The relative proportions of different types of epithelial cells can be used as broad markers of the endocrine environment. Several indices of cornification and keratinization have been used; in general the fertile period

can be crudely predicted by calculating the percentage of epithelial cells that appear anuclear when using a modified Wright-Giemsa stain (Fig. 210-4). Breeding should be attempted throughout the period when more than 75% of epithelial cells are anuclear because in most bitches this coincides with the fertile period.

However, there is great variation among bitches, and in some cases the percentage of cornified cells reach nearly 100% as early as 9 days before or as late as 2 days before ovulation. Conversely, in some cases peak values of anuclear cells may reach only 60%. Therefore changes in the vaginal cytology cannot be used to accurately time ovulation prospectively. Nevertheless, vaginal cytology permits monitoring of the normal progress of proestrus, and waiting for significant cornification allows unnecessary testing, transportation, or breeding to be avoided until the proestrus rise in estrogen is nearly complete.

As previously discussed, at the end of the fertilization period the vaginal smear rapidly becomes dominated by small- and intermediate-sized epithelial cells, cellular debris, bacteria, and polymorphonuclear leukocytes; the anuclear cell index declines dramatically. This time has been referred to as the onset of vaginal metestrus, and it is important to note that natural mating or vaginal insemination is rarely fertile when performed after this stage. In view of this, vaginal cytology is extremely valuable for demonstrating the end of the fertilization period, an event that is often not clear when using qualitative progesterone ELISA tests.

Changes in Vaginal Fluid

Measurement of the electrical resistance of the vaginal fluid (vaginal wall) has been purported as being useful for detecting the optimal time for breeding. This method is used to detect the optimal time of insemination in fox vixen. However, we recently used a commercial probe to measure electrical resistance daily in 48 bitches and found that only in two bitches were any useful trends apparent.

Similarly, the measurement of vaginal glucose concentration has failed to stand up to scientific scrutiny for the prediction of the optimal time to breed.

However, in a small number of bitches crystallization of mucus collected from the anterior vagina has been found to develop after the peak in plasma estrogen concentration. Assessment of the mucus, which originates from cervical glandular tissue, may be useful in combination with vaginal cytology for determining the optimal mating time.

Vaginal Endoscopy

Vaginal endoscopy (vaginostomy) is the examination of the luminal surface of the vaginal mucosa using a rigid endoscope. The principle underlying the technique is that endocrinologic changes influence the nature of the epithelium (as discussed previously) and therefore the appearance of the vaginal wall.

Vaginoscopic examination is well tolerated in most nonsedated bitches that are in proestrus or estrus. Examination is normally performed with the bitch standing. In most cases it can take as little as 2 minutes to make an evaluation of the stage of the cycle. The evaluation is based on assessment of the appearance of the vaginal wall (i.e., the mucosal fold contours and profiles and the color of the mucosa and of any fluid present) and the changes in this appearance at specific times of the estrous cycle.

During anestrus the vaginal mucosa is relatively thin; therefore, when examined endoscopically it is flat and dry in appearance. Furthermore it has a red coloration because the submucosal vasculature is visible. At the onset of proestrus the mucosa becomes thickened and edematous as a result of the increase in plasma concentrations of oestrogen. Therefore the mucosal folds appear greatly enlarged, thickened, and edematous and have a pink or pink/white color. Serosanguinous fluid can be observed within the lumen and may be seen to exit from the cervix.

Fig. 210-4 Schematic relationship among ovulation, plasma progesterone concentration, and the percentage of cornified epithelial cells.

As proestrus progresses, the mucosal surface becomes progressively less pink and typically appears white in color because the thickened mucosa prevents the underlying capillaries that were visible during anestrus from being seen. In very late proestrus or early estrus at approximately the same time as the LH surge, there is a progressive shrinking of the folds that is accompanied by further pallor. These effects are the result of an abrupt withdrawal of estrogen. Estrogen concentrations decline rapidly during and after the LH surge. Subsequently over the next several days mucosal shrinkage is accompanied by gross wrinkling of the mucosal folds that now become distinctly angulated and retain a dense cream to white color.

The onset of the fertile period can be detected by observing the onset of mucosal shrinkage without excessive angulations, whereas gross shrinkage of entire mucosal folds with obvious angulation is characteristic of the fertilization period.

Breeding is best planned approximately 4 days after the first detected mucosal shrinkage or at the onset of the period of obvious angulation of mucosal folds. The end of the fertilization period can be detected by observing sloughing of the vaginal epithelium (see section on Exfoliative Vaginal Cytology earlier in the chapter) and development of a variegated appearance to the color of the mucosal surface.

Observation of Follicular Dynamics Using Ultrasound

It has been clearly demonstrated that the ovaries of a bitch can be identified using real-time diagnostic B-mode ultrasound. In some bitches there is significant amount of fat within the ovarian bursa, which makes imaging difficult. However, with careful and repeated examination it is possible to monitor follicular growth and detect the time of ovulation. In general, ovulation is difficult to identify because follicles do not collapse, changes in echogenicity are not always consistent, and new corpora lutea also have central fluid-filled cavities similar to those of the follicles.

Follicles appear as anechoic (black) structures that increase in size throughout proestrus and estrus to reach approximately 8 mm in diameter just before ovulation. Although difficult, it is possible to determine the time of ovulation using ultrasound. Usually there is an apparent decrease in the number of large anechoic follicles or their complete disappearance because of an increase in echogenicity and/or a related apparent decrease in follicle size. The absence of anechoic structures may be best detected by repeated examination, during which it can be seen to persist for 1 to 2 days commencing approximately at the time of ovulation. It is often followed by the reappearance of anechoic structures in the ovaries, representing the early developing corpora lutea. Corpora lutea generally have thicker walls than preovulatory follicles and also

contain central fluid. Cavitated corpora lutea are visible for several days to 2 weeks after ovulation. In clinical practice using ovarian ultrasound to determine the fertilization period has little clinical application at the present time because of the difficulties in imaging the ovaries and the requirement for frequent examination.

CONCLUSION

When considering the optimum time to breed, an important consideration is the unique reproductive physiology of the bitch. Although there is a protracted fertilization period compared with other species, it is important to remember that the most common causes for apparent infertility are misunderstanding of the normal physiology and thus breeding at the incorrect time.

In general, the optimal time to breed is during the fertile period. However, this period is influenced by the male, and in animals with poor-quality semen or in which semen has been preserved there may be shortened survival of sperm within the female reproductive tract. Therefore understanding the normal physiology and detecting the fertilization period are among the most important aspects of investigating infertility in canine reproduction.

Use of Vaginal Cytology and Vaginal Cultures for Breeding Management and Diagnosis of Reproductive Tract Disease

BEVERLY J. PURSWELL, *Blacksburg, Virginia*

Breeding management in the dog has evolved over the last few years to a fairly sophisticated level compared to previous times. With the advent and routine use of progesterone testing in breeding management, the use of cooled shipped semen and frozen semen has allowed clinical canine reproduction to approach the level of technology commonplace in other species. Yet there remains much hearsay and lay opinion influencing the breeder and their requests for veterinary care. Vaginal cytology is a traditional technique used in breeding management. The limitations of the information gained from vaginal cytology must be appreciated by the veterinarian and the breeder. Vaginal cultures are another area in which misinformation abounds. For vaginal cultures to result in any meaningful information, the culture must be obtained correctly, and knowledge of the normal flora of the vagina must be applied to culture results. Both techniques, vaginal cytology and vaginal cultures, can be extremely informative in breeding management situations and in diagnosis of reproductive tract disease when placed in context with the total clinical picture.

VAGINAL CYTOLOGY

Vaginal cytology can be used in breeding management because of the changes that occur to the vaginal epithelium when under the influence of estrogen (also see Chapter 210). Normally the vaginal epithelium is only a few cell layers in thickness. Under the influence of estrogen, the vaginal epithelium thickens to 20 to 30 cell layers in thickness. This cornification process of the vaginal epithelium protects the vagina from the physical trauma experienced at breeding. The exfoliative cytology of the vagina reflects the cornification process by the cell types that predominate. The basal cells closest to the basement membrane are small and round and have prominent nuclei. This cell type predominates the cytology taken when the bitch is not under the influence of estrogen. As the vaginal epithelium thickens because of the influence of estrogen, the cells that are further from their basement membrane undergo cornification. These cells are large and have angular cell borders and small pyknotic

nuclei or no nuclei at all. When the bitch is in proestrus or estrus and under the influence of estrogen, the cornified cell type predominates the vaginal cytology.

Vaginal cytology is extremely helpful to the clinician in diagnosing *inflammation in the reproductive tract*. Normally only the occasional neutrophil is present in vaginal cytology. As the bitch progresses through proestrus into estrus, the neutrophils disappear altogether. This is most likely a result of the increase in thickness of the vaginal epithelium impeding the migration of neutrophils into the vaginal lumen. In cases of uterine or vaginal inflammation, the numbers of neutrophils in the vaginal cytology increase dramatically. During early diestrus there is an influx of nondegenerate neutrophils, which is considered normal for that stage of the estrous cycle. At all other times large numbers of neutrophils indicate an inflammatory process. In inflammatory processes the majority of the cells present are degenerate neutrophils.

Vaginal cytology is useful in breeding management and in detecting disease processes within the reproductive tract. Vaginal cytology indicates the influence of estrogen on the reproductive tract and the presence of inflammation. Beyond these two helpful pieces of information, it is limited in relaying other information concerning the hormonal status of the bitch. Vaginal cytology cannot accurately determine ovulation or the ideal time to breed. However, it does indicate accurately the onset of diestrus. There is a dramatic and sudden change from cornified to noncornified epithelial cells at the onset of diestrus. This determination can be useful in predicting gestation length. Most bitches whelp 56 to 57 days after the onset of cytologic diestrus.

VAGINAL CULTURE

Vaginal cultures are often requested by a stud dog owner before breeding a bitch outside of its kennel. This practice of requesting vaginal cultures is an attempt to protect the male dog from contracting disease organisms from the bitch. Without evidence of an ongoing disease process, positive vaginal cultures only reflect the normal flora that are present in a majority of bitches. A variety of bacteria are commonly isolated from the vagina of

normal breeding bitches. This clinical picture becomes further confounded when the vaginal culture is taken during proestrus and estrus. At this time it is not unusual to obtain bacterial cultures that reflect heavy growth of a single organism. It is thought that the serosanguineous discharge present during proestrus and estrus promotes the proliferation of bacteria within the vagina. Therefore results of vaginal cultures must be interpreted with this information in mind and correlated with the entire reproductive picture presented by each clinical case.

When culturing the vagina, a guarded swab culture instrument (Kalayjian Industries) is necessary to sample the anterior vagina while preventing contamination from the distal tract. The distal vagina and vestibule normally harbor large numbers of bacteria. To accurately diagnose and assess bacteria that may be present in the uterus and causing reproductive dysfunction, anterior vaginal cultures are needed because these are most reflective of the disease process.

Canine vaginal flora have been well documented in a number of studies over the last 30 years (Table 211-1). It has been observed by investigators that the normal flora of the canine vagina contain bacteria that may cause reproductive tract disease (e.g., *E. coli* and *Mycoplasma* spp.). These bacteria are opportunistic pathogens in addition to being normal flora. Their presence in the vagina does not necessarily indicate disease or infection. It is interesting to note that the same organisms found as normal flora in the canine vagina can also be found as normal flora on the penis and prepuce of the dog (Table 211-2).

There is one microorganism that, when present, always indicates an infection: *Brucella canis*. The pre-

ferred screening test for *Brucella canis* infection is serology, either by a rapid slide agglutination assay, tube agglutination test, or agar gel immunodiffusion test. Serology for *B. canis* should be a part of any prebreeding management strategy.

When interpreting the results of a vaginal culture, the clinician must consider a number of other factors. The medical and reproductive histories are helpful in identifying previous problems with infections or infertility. Vaginal cytology should always be collected and evaluated in concert with vaginal cultures. When there is no evidence of inflammation in the vaginal cytology, the results of the culture most likely reflect normal flora. If there is an abnormal vulvar discharge, inflammation is documented by vaginal cytology, or the bitch is exhibiting systemic signs of disease, the vaginal culture is essential for identifying the causative organism and determining the appropriate antimicrobial therapy.

Other Diagnostic Tests

Other diagnostic tests that may be indicated include vaginoscopy and ultrasonography. These studies assist in adequately and appropriately diagnosing the location and cause of reproductive disease. Vaginoscopy is essential in determining the physical source of a vulvar discharge and can be useful for determining the stage of the reproductive cycle (also see Chapter 210). Ultrasonography often demonstrates the presence of uterine pathology by allowing visualization of fluid within the uterine lumen or demonstrating cystic endometrial hyperplasia.

Antimicrobial Therapy

Hard-and-fast rules for management based on culture results are untenable when culturing sites that are not normally sterile. Vaginal culture and cytology are invaluable when diagnosing reproductive tract disease, but routine cultures in normal animals must be interpreted with great care. Prophylactic antibiotics before and during breeding have been shown to be *detrimental* in the normal animal. Inappropriate antimicrobial therapy can alter the vaginal flora, causing overgrowth of opportunistic pathogens and creating abnormal vulvar discharges. Thus such use of antibiotics must be avoided.

Endoscopic Transcervical Insemination

MARION S. WILSON, *Te Kuiti, New Zealand*

It is widely recognized in many species that thawed frozen semen must be deposited into the uterus rather than vaginally to achieve good conception rates. The options available to achieve intrauterine semen deposition are surgical or transcervical insemination (TCI). In many parts of the world the surgical option is the method of choice in the bitch because it is easy to perform, without any major learning period. However, surgery has some drawbacks, including the risks associated with general anesthesia and surgery and the restriction to a single insemination. Accordingly many owners and veterinarians prefer a nonsurgical option.

I developed the TCI technique using a rigid endoscope specifically to deposit frozen semen into the uterus of the bitch. In researching the technique several features relating to the anatomy of the canine reproductive tract were identified. These points are relevant to endoscopic TCI and are considered first, followed by a description of relevant procedures for TCI.

ANATOMY

The cranial vagina (paracervix) is dominated by the dorsal median fold (DMF), which significantly reduces the vaginal lumen in the approach to the cervix. The restricted vaginal lumen limits the diameter of equipment that can be passed through the area. This feature, together with a particularly long vagina in the bitch, limits the number of endoscopes suitable for the technique. The DMF ends cranially at the vaginal portion of the cervix, which exists as a distinct tubercle (cervical tubercle). The paracervix is limited cranially by the fornix, which is a slitlike space cranioventral to the cervical tubercle. It appears as a blind end when viewed through the endoscope and is another important landmark. The cervix lies diagonally across the uterovaginal junction with the canal of the cervix directed craniodorsally from the vagina to the uterus. Consequently the external os is located ventrally in the cervical tubercle.

EQUIPMENT

The endoscope identified as meeting the criteria with regard to length and diameter is a rigid extended length cystourethroscope.* An 8-Fr-gauge urinary catheter is used for insemination in the majority of bitches, although a 6-Fr-gauge is sometimes required in small or maiden

bitches. A specially designed platform is used to restrain the bitch in the standing position; the platform provides a tie point to the dog's collar and a canvas band around the abdomen to restrict sideways movement and discourage any attempt to sit. A hydraulic chair together with a hydraulic table for the platform ensures the optimum position of the bitch relative to the operator during the procedure; this is particularly important when the endoscope is being used without a camera. Bitches in oestrus exhibiting standing behavior show excellent tolerance to the technique; sedation has never been necessary.

TECHNIQUE

The endoscope is introduced into the vagina, taking care to avoid the clitoris and urethral orifice. It is advanced through the vaginal folds by observing the direction of the vaginal lumen. In proestrus and early oestrus the rounded vaginal folds can make advancing the endoscope more difficult as they tend to fill the lumen; as oestrus progresses, dehydration of the folds results in a more obvious route forward. The DMF and crescentic lumen represent an important landmark in locating the cervical os. At this point the lumen can be quite narrow in some bitches, requiring manipulation of the endoscope to the widest space. This may result in the endoscope being pushed to one side of the DMF rather than continuing ventrally under the DMF. The ventral location of the os means that it is not immediately obvious and the scope has to be directed under the cervical tubercle until the os, located in the center of a rosette of furrows, can be identified. The catheter is advanced into the cervical os by manipulation of the endoscope and catheter. The rigidity of the endoscope is used to move the cervical tubercle, line up the os, and change the angle of the canal.

Once the tip of the catheter is introduced into the os, it is advanced steadily using a twisting movement to aid its passage through the cervical canal; it is passed in as far as it will go without force. The semen is inseminated slowly under continual observation to ensure that there is no significant backflow of semen into the vagina. If this happens the catheter should be relocated, either further in or back slightly, and insemination begun again.

PRACTICAL CONSIDERATIONS

The cost of the equipment makes it a major decision to take on board endoscopic TCI in a practice. Veterinarians must understand what they can expect from the technology,

* Storz Extended Length Cystourethroscope: telescope 30° 325 B, 3.5-mm sheath, 027KL, Bridge 027NL.

how easy the techniques are to learn, and what problems and results they can expect.

Theoretically the technique is very simple but takes time, patience, and practice to perfect. The attachment of a video camera to the endoscope allows for direct training by an experienced operator and is extremely helpful in training. However, many people have taught themselves to perform TCI. Most find the prospect of getting the catheter into the os to be a challenge they can confidently overcome in a relatively short time. However, mastering the peculiarities of all breeds and sizes takes much longer.

The Limiting Factors/Problems

For the technique to be widely adopted, it is essential that it can successfully be applied to all, or at least, most bitches. It is also important that the majority of bitches can be inseminated using the same endoscope. Looking at the vast array of breeds presented with regard to size and shape, this would seem unlikely, but for the most part it is possible.

Length of the Vagina

So far no bitch has been examined when the cervix is beyond the reach of the equipment described; thus vaginal length is not a limiting factor, provided the correct endoscope is purchased.

Diameter of the Paracervix

The one limiting factor identified thus far is the amount of space available in the paracervix. In a small percentage of bitches it is impossible to advance the endoscope through this area. This occurs in some maiden bitches of small or medium-sized breeds and in some toy breeds such as the Chihuahua. Endoscopes of smaller diameter are available, but they are also considerably shorter and only solve the problem for toy breeds when the vaginal length is short. The standard endoscope described here has been used successfully on many small/toy breeds, including pugs, Pekingese, griffon Bruxellois, cavalier King Charles spaniels, and miniature dachshunds; thus it is suitable for the majority of bitches. More recently a smaller-diameter sheath has been developed for use with the standard telescope, solving the space problem in some bitches; however, a 6-Fr-gauge catheter is required for insemination with this sheath. With the very small toy breeds restraint of the bitch while trying to manipulate a relatively long scope is a large part of the problem. In these cases sedation may improve success.

Identification of the Cervical Os

Theoretically once the endoscope has passed through the paracervix it should be possible to catheterize all bitches. The ability to identify the os comes from experience (i.e., appreciating what it looks like, where it is usually located, and how to search for it when it is not obvious). Some bitches have folds that can be mistaken for the os, but obviously there is no opening for the catheter. Fluid issuing from the os identifies the correct location.

Cannulation of the Cervix

Ensuring that the catheter advances once the tip is with the os depends on application of appropriate pressure and at the correct angle to account for the angle of the cervical canal. Sometimes progress is limited by the diameter of the canal, and a smaller-gauge catheter is necessary.

Visibility

Vaginal discharges resulting in poor visibility can cause significant problems, particularly in the learning phase of TCI.

Most of the problems encountered result from not appreciating the anatomy of the female reproductive tract or not having developed the knack of manipulating the endoscope and catheter together. However, not all bitches are easy to catheterize. Difficult entry angles, ongoing poor visibility, and fidgeting patients occasionally defy all attempts from even the most skilled operator.

Confidence in the Technique

Intrauterine Deposition

With visualization of the cervix there can be no doubt that the catheter is intrauterine. Continued viewing of the insemination process ensures that the semen is deposited in the uterus. A video camera allows the client and the operator to observe the intrauterine deposition of the semen. This is a particularly positive aspect of videoendoscopy technology.

Safety

The risk of trauma or infection resulting from the procedure is an important consideration. It is difficult to imagine that the plastic urinary catheter could ever perforate the vaginal or uterine wall during estrus unless a pathologic condition preexisted. However, the paracervical area can be traumatized by the use of inappropriate force with the endoscope. If advancing the endoscope causes obvious discomfort to the bitch, the procedure should be stopped. It has been suggested that TCI could introduce infection to the uterine environment. During proestrus and oestrus bacteria are routinely isolated from the uterus and vagina apparently without causing any problems, perhaps because of a greater resistance to infection at this time. Therefore it is reasonable to assume that advancing a catheter from the vagina to the uterus at this time will not cause any problems. However, care must be taken to prevent introduction of new infections as a result of inadequately cleaned equipment or from environmental contamination caused by poor technique.

The equipment can be readily cleaned and disinfected, and standard techniques and procedures should be established.

Frozen Semen

This technique provides for the intrauterine deposition of semen, a vital part of frozen semen technology. Equally important to the successful use of frozen semen are the timing of insemination, semen quality, and bitch fertility. Endoscopic TCI, like any other intrauterine insemination method, will be successful only if all of these factors are taken into account.

TCI also can be performed using the so-called *Norwegian method*. This method uses a nylon sheath and metal catheter, which are produced in three sizes to suit different-size bitches. The technique requires palpation and fixation of the cervix through the abdominal wall; manipulation of the cervix enables catheterization with the metal catheter. The Norwegian method has been described in several previous reports.

Results from a trial comparing Norwegian and endoscopic TCI demonstrated that conception rates of 83.3% and average litter size of 7.5 were possible using TCI in bitches of unknown breeding history. These results compare favorably with results from other trials using frozen semen, indicating there are no undesirable effects from TCI. There are no trials making a direct comparison between surgical and endoscopic TCI; thus it is impossible to know if the results are better using TCI.

The ability of repeat inseminations has been reported to increase conception rates or litter size. TCI allows for this approach, whereas surgery does not. When the semen is of lower quality, repeat inseminations allow more semen to be inseminated over an extended period. Repeat inseminations are also useful when the bitch is difficult to time relative to phase of the estrus cycle.

Fresh or Chilled Semen

In any insemination, if the semen can be deposited intra-uterine, it is reasonable to expect that the results may be better than vaginal deposition; this applies to both chilled and fresh semen, particularly when semen quality is poor. Using TCI for fresh and chilled inseminations not only results in excellent conception rates and litter sizes but provides the opportunity to develop experience and expertise for many more situations.

Other Uses

The endoscope also can be used for routine vaginoscopy to determine the progression through the reproductive cycle, as well as for diagnostic vaginoscopy, cystoscopy,

and hystero-graphy. TCI has been used to study the intra-uterine environment with respect to microbiology and cytology throughout the reproductive cycle of the bitch, providing valuable research data (Watts and Wright, 1995). When examinations are performed during anestrus and diestrus, the vaginal walls are thinner and more susceptible to trauma; extreme care must be taken in these situations. Bitches not in standing heat do not tolerate the endoscope very well; thus sedation is usually required in these cases. Sedation diminishes the dog's reaction to inappropriate manipulation of the endoscope, emphasizing the need for extreme care. Air insufflation is also helpful for examination during anestrus and diestrus. The uterus is likely to be more susceptible to infection during diestrus when under the influence of high progesterone levels. Special care and aseptic examination technique are crucial at this stage of the cycle.

Presumably the routine ability to catheterize the cervix will lead to the development of new diagnostic procedures and treatments.

Pregnancy Loss in the Bitch

JONI L. FRESHMAN, *Colorado Springs, Colorado*

Pregnancy loss in the bitch can occur for a multitude of reasons. Pregnancy loss earlier than 21 days is difficult to diagnose because of the unavailability of a definitive pregnancy test for this time period. Pregnancy can be diagnosed by abdominal ultrasound as early as 16 to 18 days after ovulation but more reliably from days 20 to 26. Relaxin assay (Witness Relaxin, Synbiotics) can diagnose pregnancy later than 21 days from the luteinizing hormone (LH) surge, and radiographs are useful for pregnancy diagnosis after 42 to 45 days of gestation. Abdominal palpation is not sensitive enough to document pregnancy for the purposes of confirming pregnancy loss.

Fetal death in the first half of pregnancy typically results in resorption of the fetuses or unobserved abortion. Fetal death in the second half of gestation typically results in abortion or stillbirth, although resorption may still occur. Abortion may not be recognized because the bitch may ingest the aborted material. Fetal death in late gestation in the presence of continuing luteal influence may also result in mummification when fetal and placental fluids are resorbed, leaving dried structures in the uterus.

DIAGNOSTICS

The most useful step in diagnosis and prevention of future pregnancy loss is submission of the aborted fetus and placenta, in total, to a diagnostic laboratory experienced in reproductive histopathology. The materials should be submitted immediately, refrigerated but not frozen. Vaginal swabs from the bitch for culture and serum from the bitch for titers may also be useful. Aborting/resorbing bitches should have a diagnostic panel to include a complete blood count, serum biochemistry panel, urinalysis, *Brucella canis* test, serum progesterone test, and vaginal cytology, with culture and sensitivity if inflammation is evident.

Pregnancies of bitches with a history of pregnancy loss should be monitored by ultrasound, ideally at least weekly. Fetal heart rates are good indicators of fetal health and should be in the 170 to 220 beats/min range. Rates should vary with the fetus's activity and sleep status.

There are many potential causes of pregnancy loss in the bitch. These can be separated into two main categories, infectious and noninfectious. Even with use of all available diagnostics, some cases of pregnancy loss remain idiopathic.

INFECTIOUS CAUSES OF PREGNANCY LOSS

Infectious causes of pregnancy loss are those most commonly diagnosed. Aborted fetuses, placentas, and vaginal

swabs from the bitch should be submitted for testing. In addition, analysis of serum submitted from the bitch may be helpful in diagnosis.

Brucella canis

Brucella canis is a gram-negative, aerobic reproductive pathogen in the dog, most commonly spread by contact with infected aborted fetuses, placentas, infected vulvar discharge, and urine (Greene and Carmichael, 2006). Although brucellosis can cause early embryonic death (10 to 20 days), it most commonly causes abortion at 45 to 59 days of gestation (Greene and Carmichael, 2006). Initial screening for brucellosis is made with the rapid card agglutination test (RCAT, Synbiotics). This test is very sensitive, and a negative initial test can be relied on unless the bitch has been receiving antibiotics. Early infection may also be negative, and testing 4 to 8 weeks after exposure is recommended. A test that is initially positive but clears with the addition of the included chemical 2-mercaptoethanol can result from cross-reacting antibodies or from immunoglobulin (Ig)M antibodies, denoting an early *Brucella* infection. These dogs should have tests repeated in 30 days or have other diagnostic tests performed. The cytoplasmic antigen agar gel immunodiffusion (AGIDcpa) test is a specific confirmatory test, but it may not become positive until 4 weeks after the RCAT (Hollet, 2006). Blood cultures typically are positive at 2 to 4 weeks after infection (Greene and Carmichael, 2006). Because of labor and expense, blood cultures typically are not used as a first test for *Brucella*. Brucellosis can be a difficult organism to grow; thus multiple negative cultures (three) are required to rule out infection.

Antibiotic therapy for canine brucellosis is controversial. Antibiotics are not proven to cure the disease since dogs may relapse after apparent remission. *Brucella canis* does pose a risk to immunosuppressed humans. If treatment is attempted, the bitch should be ovariohysterectomized and isolated from other dogs. Antibiotics used are a combination of streptomycin 20mg/kg every 24 hours for 14 days and tetracycline 30mg/kg every 12 hours for 28 days (Greene and Carmichael, 2006). Recently the use of long-term enrofloxacin has resulted in regression of the disease and production of puppies by infected dogs and bitches (Wanke, Delpino, and Baldi, 2006). The clinician should understand the adverse effects of these antibiotics. Canine brucellosis is a reportable disease in many states. Procedures for management of infected kennels have been published (Hollet, 2006).

Other Bacteria

The bitch's reproductive tract contains normal flora (Box 213-1) (Bjurstrom, Linde-Forsberg, 1992), thus positive vaginal cultures are not diagnostic for infection. Any bacterial species is capable of overgrowth and can cause infection and pregnancy loss. Diagnosis requires cultures from aborted material and inflammatory cytology from vagina or uterus. Submission of fetal stomach contents is particularly valuable.

Normal bitches given prophylactic antibiotics developed increased numbers of *Escherichia coli* and *mycoplasma*, and two out of five developed vaginal discharge (Ström and Linde-Forsberg, 1993). For this reason empiric antibiotic use in the bitch is strongly discouraged. Although most sources consider the canine uterus to be a sterile environment, one study found uterine flora in 68% of bitches studied (Baba et al., 1983). In this study, these organisms were most commonly *staphylococcus* spp. and *mycoplasma* spp. No histopathologic abnormalities were seen in the uteri of these bitches.

Salmonella

Salmonella spp. are not found as normal flora in the bitch's reproductive tract. *Salmonella panama* has been identified as the cause of canine abortions. Infection can occur by contact with infected food, water, or fomites. Diagnosis is by culture of aborted materials or vaginal discharge. Cure of *Salmonella* infection has been reported with trimethoprim sulfa antibiotics; however, treatment may simply prolong the carrier state (Johnston et al., 2001). Prophylactic antibiotics increase the risk of infection by decreasing the number of organisms needed to cause infection because of suppression of normal flora. The infected bitch should be isolated, and excellent sanitation should be provided. Removing her from the breeding population may be necessary. Owners should be cautioned about zoonotic potential.

Campylobacter

Campylobacter has also been documented as a cause of abortion and fetal resorption in the bitch. The bitch may be otherwise asymptomatic. Aborted materials and vaginal cultures need to be submitted in special media. Owners should be cautioned about the zoonotic potential of *campylobacter*. Treatment is with erythromycin 10 to 15 mg/kg every 8 hours orally for 10 to 14 days.

Box 213-1

Selected Common Normal Vaginal Flora in the Bitch

- Pasteurella
- Group B streptococcus
- *E. Coli*
- Enterococci
- Bacteroides
- *Staphylococcus intermedius*
- *Mycoplasma*

Mycoplasma/Ureaplasma

These organisms have been documented as normal flora in the bitch. *Ureaplasma* has alternatively been considered an obligate reproductive pathogen. These organisms are most likely to cause reproductive dysfunction in overcrowded kennel situations. Dispersal of dogs decreases the number of organisms. Treatment with antibiotics reduces the number of organisms present, but the numbers rise once antibiotics are stopped unless husbandry is addressed.

Canine Herpesvirus

Canine herpesvirus (CHV) is a common, mild, upper respiratory infection in dogs, and as such is a ubiquitous organism. Bitches infected during their last 3 weeks of gestation develop a systemic infection and placentitis, which results in abortion. Mummification of fetuses can also occur. The bitch is otherwise typically asymptomatic. Puppies exposed during their first 3 weeks of life are also at high risk of death. Recurrence in the same bitch is uncommon but can occur. Diagnosis of CHV is by examination and virus isolation of the aborted fetus and/or placenta. The infected placenta is underdeveloped and congested with gray-to-white foci. No treatment is available for CHV abortion. However, isolation of the pregnant bitch from other dogs for the danger period (3 weeks' prepartum through 3 weeks' postpartum) can prevent infection. Vaccination is available in Europe (Merial).

Canine Parvovirus 1 (Minute Virus of Canines)

Minute virus of canines (canine parvovirus 1) has been documented as a cause of fetal death and resorption in early pregnancy, most notably the first trimester (Carmichael et al., 1991). No clinical illness is seen. The viral infection is short, with a 2-week incubation and disappearance of the virus about 2 weeks after fetal death (Carmichael, Schlafer, and Hashimoto, 1981). Bitches infected in the last trimester usually deliver normal puppies. Diagnosis is difficult since there is only one cell line that currently supports viral isolation. There is no known treatment.

Other Viruses

Other viruses have been implicated in canine pregnancy loss. A calicivirus has been isolated from the canine vaginal tract in cases of vesicular vaginitis. Calicivirus does cause abortion in other species and may do so in the canine. Virus isolation from aborted material is recommended for diagnosis.

Canine distemper virus (CDV) can cause placental separation and subsequent pregnancy loss. Other clinical signs consistent with CDV should be present.

A canine vaccine contaminated with bluetongue virus was documented to cause canine abortion (Wilbur et al., 1994). Natural exposure to bluetongue virus and abortion have not been identified.

Protozoa

Toxoplasmosis is an uncommon cause of canine abortion. Ingestion of cat feces or infected raw meat can produce infection. In experimental conditions injection with *Toxoplasma* caused abortion 4 to 6 days after inoculation,

with systemic illness appearing 3 to 5 days after inoculation. Diagnosis is made with paired serum samples from the bitch. Avoiding exposure to feline feces and raw meat should prevent infection.

Neospora caninum has been transmitted transplacentally in experimental conditions. Although it is unknown if this occurs naturally, *Neospora* may be responsible for cases of abortion previously attributed to *Toxoplasma*.

NONINFECTIOUS CAUSES OF PREGNANCY LOSS

Maternal Health

Maternal disease can cause pregnancy loss. Bitches should be evaluated for endocrine diseases such as hypothyroidism, diabetes mellitus, hypoadrenocorticism, and hyperadrenocorticism, which are all documented as causes for pregnancy loss in women. In borzoi hypothyroidism was identified as the cause of abortion and mummified fetuses (Johnson, 1987).

Uterine health can also play a role in pregnancy loss. Cystic endometrial hyperplasia (CEH) can create a uterine environment that will not support fetal growth to term. Diagnosis of this disease is made only by histopathologic examination of uterine biopsies. No known treatment is available.

Bitches decrease production of puppies between 4 and 8 years of age, with increasing effect after 8 years (Fox, 1963). This may be to the result of a combination of CEH and aging of ova.

Dietary deficiencies in the bitch may affect fetal survival. Deficiency of vitamin A, manganese, or iodine may cause fetal loss. However, these are unlikely in dogs fed a good commercial diet.

Abdominal trauma is an uncommon cause of pregnancy loss. However, significant abdominal trauma can result in abortion or resorption. History and physical examination should reveal this cause. Risky exercise should not be continued during pregnancy. Dogs should be walked and exercised on the flat as they are willing; however, strenuous exercise such as field training or exercise that carries risk of trauma such as agility, herding, or fly ball should be suspended during pregnancy.

Maternal exposure to chemicals may also affect fetal health. Heavy metals, solvents, and plastics may all have adverse effects. A careful history of exposure before and during pregnancy is important. In addition, an increased abortion rate in wives of men exposed to these chemicals has been documented; thus exposure of the sire should also be considered.

Finally, dystocia contributes to late pregnancy loss. The average term stillbirth rate is 2.2% to 4.5%. The incidence of fetal mortality increases to 22.3% with dystocia (Johnston et al., 2001). Late pregnancy can be monitored with a uterine monitoring system (Whelpwise). This alerts the owner and veterinarian to a problem earlier than may otherwise occur, enabling intervention with problem deliveries.

Gamete Aging

In bitches that are bred too early in their cycle, sperm may be aged by the time fertilization occurs. Conversely,

bitches bred late in their cycle may have ova that are at the end of their functional lives. In humans this increases the risk of abortion. It is unknown if this is also true in the dog.

Genetic and Chromosomal Causes

The fetal mortality rate is higher in purebred than hybrid dogs (Fox, 1963). In a study of outbred and inbred studs bred to outbred and inbred bitches, the inbred producers had a decreased conception rate and fewer live births (Wildt et al., 1982). Evaluation of pedigrees of the dam and sire is useful when there is pregnancy loss. Programs are available to calculate the coefficient of inbreeding (COI). Breeding the bitch to an unrelated proven male may be helpful.

In women 50% of human fetuses that implant are lost in the first or second trimester (Jacobs, 1982). Genetic causes, especially chromosome loss, are responsible for many. Lethal defects cause early embryonic death and resorption. The incidence of such losses is unknown in the canine. Karyotyping of aborted fetuses shows gross chromosomal defects such as triploidy or x-monosomy, but does not diagnose single gene defects (Post, 1995). The canine genome project may help advance knowledge in this area.

Drug Administration

The critical period for embryotoxicity in the bitch is 6 to 20 days after LH surge. Drug administration should be avoided during this time period. Certain drugs are known to be a risk for pregnancy loss (Box 213-2).

Hypoluteodism

The lack of sufficient progesterone to maintain pregnancy is an extremely uncommon cause of pregnancy loss in the bitch. Because progesterone decrease rapidly follows abortion from any cause, this decline may be mistaken as the cause itself. Thorough diagnostics should be performed to rule out other causes, especially infectious ones, before any progesterone supplementation.

In the bitch serum progesterone higher than 2 ng/ml is required to maintain pregnancy. Serial monitoring of progesterone can be performed. Values higher than 20 ng/ml are common. Levels of 5 to 10 ng/ml may necessitate

Box 213-2

Drugs That May Cause Pregnancy Loss

- Dexamethasone
- Misoprostol
- Verapamil
- Diltiazem
- Xylazine
- Pentobarbital
- Chemotherapeutics
- Organophosphates

Table 213-1

Pharmacologic Progesterone Supplementation in the Bitch

Drug	Dose
Progesterone in oil	2-3 mg/kg q24-48h IM

IM, Intramuscularly; PO, orally.

weekly or every-other-day monitoring. Supplementation is provided if the progesterone level reaches 5 ng/ml with a week or more left in gestation. Two options for progesterone supplementation exist (Table 213-1). When using progesterone in oil, monitor to maintain a serum progesterone level of 10 ng/ml. Ally-trenbolone (Regumate) has an advantage in that it does not cross-react in progesterone assay; thus the endogenous progesterone level can continue to be monitored. The pregnancy should be monitored with ultrasound because of the increased risk of pyometra.

Progesterone supplementation should be avoided during the first trimester because of the risk of masculinizing female fetuses. In addition, ovulation timing is necessary to document the correct due date. Progesterone supplementation should be stopped 2 to 3 days before expected parturition so that fetuses are not retained too long. Finally, milk production is often inadequate, possibly because of prolactin suppression; thus milk supplementation of pups often is needed.

False Pregnancy in the Bitch

DANA R. BLEIFER, *Woodland Hills, California*

False pregnancy, also called *pseudopregnancy* or *pseudocyesis*, is a common condition in intact bitches. The exact incidence may not be known, but one report found 87% of intact females to exhibit signs of false pregnancy two or more times in their lifetime (Janssens, 1986). On rare occasions it is also seen in spayed females. Usually clinical signs are mild and often ignored or unnoticed; but when disorders are manifest or if behavioral clinical signs are present, treatment may be warranted.

CLINICAL SIGNS

Clinical signs of pseudopregnancy are not associated with an endocrine abnormality; they are related to normal elevated plasma concentration of prolactin (England and Harvey, 1998). As progesterone concentration decreases in the second half of diestrus, prolactin concentration increases. A rise in the prolactin also can be seen if plasma progesterone drops for other reasons such as ovariohysterectomy during the luteal phase. Progesterone may also decrease suddenly consequent to spontaneous or pharmacologic abortion. Because all intact bitches experience this drop in progesterone and rise in prolactin in diestrus, one could say all bitches experience a physiologic pseudopregnancy. What makes some bitches experience clinical or overt pseudopregnancy is unclear. Perhaps it is excessively elevated prolactin concentration (Gobello, de la Sota, and Goya, 2001) or maybe an increase in sensitivity to the hormone in those bitches (Gobello et al., 2001). There are no differences in progesterone concentrations between pregnant and nonpregnant bitches, nor is there a difference in progesterone concentrations in bitches with overt and covert false pregnancy. Thus any bitch with a history of false pregnancy should be spayed in late anestrus, early proestrus, or anytime that progesterone levels are low.

Clinical signs of overt pseudopregnancy vary. The most common sign is mammary gland enlargement, with or without milk production. In some cases lactation may result in mastitis. Other signs associated with whelping may be observed such as nesting, nursing a "litter" of toys, nervousness, aggression, dullness, or a milky vulvar discharge. Signs of pseudopregnancy usually manifest 6 to 12 weeks after estrus and may last from weeks to months. Cases manifesting behavioral changes only may be difficult to diagnose; but when there is a recurrent cyclic pattern, pseudopregnancy should be considered. The severity of clinical signs also can vary dramatically. Often it is the severity of clinical signs or the necessity of participating in a show, performance trial, or work that dictates the need for treatment.

DIAGNOSIS OF THE AFOREMENTIONED CLINICAL SIGNS

Differential diagnosis of the aforementioned clinical signs includes pregnancy, pyometra, and ovarian remnant syndrome in spayed bitches. Generally the medical history, physical examination, ultrasound to rule out pregnancy or pyometra, vaginal cytology to identify cornification, and hormone testing for progesterone and/or estrogen can differentiate the conditions. Mammary gland development has also been reported in hypothyroidism, but it is unclear if the hypothyroidism was a cause or a coincidence with a normal false pregnancy (Chastain and Schmidt, 1980). The first condition to rule out is true pregnancy. Depending on the number of weeks following estrus, the fetus should be evident by ultrasound if longer than 25 to 28 days or by radiograph if longer than 50 days. Even if the time period exceeds gestational length, it is wise to rule out a mummified fetus.

If the clinical signs include lethargy, poor appetite, or vulvar discharge, pyometra, hydrometra, or mucometra should be ruled out. Ultrasound can identify the presence of fluid in the uterus. If there is a vulvar discharge, a vaginal cytology demonstrating excessive white blood cells also may increase the suspicion of pyometra. In the case of a closed cervix pyometra, there may be an elevated systemic white blood cell count with an immature neutrophilia (see Chapter 218).

In spayed bitches an ovarian remnant should be ruled out if there is a cyclic pattern to the pseudopregnancy signs. Vaginal cytology performed at the time of suspected estrus should show cornification of the vaginal epithelial cells if there is active ovarian tissue. Progesterone levels higher than 2 ng/ml in the weeks following a suspected "heat cycle" would also confirm the presence of ovarian tissue. Removal of the ovarian remnant is the treatment of choice. It is my experience that the ovarian remnant is easier to find during a heat cycle.

THERAPY

The majority of cases of pseudopregnancy require no treatment. False pregnancy does not predispose the bitch to reproductive disease. Spontaneous resolution usually occurs. After the luteal phase, serum prolactin is highest and then gradually declines. After a few weeks clinical signs should start to regress (typically about 12 weeks after estrus). Restricting food and water intake and increasing exercise have been suggested to shorten this period (Lawler et al., 1999). Sedatives can be used to minimize certain behaviors, but phenothiazines such as acepromazine maleate (Promace, Fort Dodge) should be

avoided. Phenothiazides are dopamine antagonists and may increase prolactin levels. Although diuretic therapy may decrease mammary gland secretions, such treatment should only be used with great care.

Occasionally pseudopregnancy persists for many months or years. The reason for this is unknown but may relate to lack of hormonal interaction between the pituitary/hypothalamus and the ovary. The recurrence of false pregnancy in spayed females is perplexing but may be related to the point in their cycle at which they were spayed, as well as other hormonal interactions.

Reproductive hormones have been used successfully to treat pseudopregnancy. Progestogens work well by suppressing the release of prolactin, but signs may recur if the progestogen is discontinued quickly. The dosage should be decreased gradually. Megestrol acetate (Ovaban, Schering-Plough) dosed at 2.5 mg/kg every 24 hours orally for 8 days is the only approved product available in the United States. Estrogen and androgen treatments have also been successful and are thought to work in the same way as progesterone. Both estrogens and androgens may be associated with adverse side effects; thus they should be used carefully if at all for this purpose. Until recently mibolerone (Cheque Drops, Upjohn) was available in the United States and was a very effective treatment. There are a variety of suggested dosages, but typically mibolerone 16 mcg/kg every 24 hours orally for 5 days diminishes clinical signs.

The treatment of choice for false pregnancy in the bitch now appears to be the antiprolactin drug cabergoline (Dostinex, Pharmacia & Upjohn). Cabergoline is a long-acting serotonin antagonist. A dosage of 5 mcg/kg every 24 hours orally for 5 days seems to be optimal (Jochle et al., 1989). The drug typically is well tolerated and very effective, but it is also expensive. The dopamine agonist bromocriptine mesylate (Parlodel, Sandoz) is also effective but associated with a high incidence of

gastrointestinal side effects. Compounding bromocriptine into a suspension and gradually increasing the dosage up to 10 mcg/kg daily for 19 days may decrease some side effects. Concurrent treatment with metoclopramide HCl (Reglan, Robbins) may be used to reduce vomiting; this drug can oppose dopaminergic action. Other dopaminergic agonists have been used successfully but are not readily available in the United States.

Dystocia Management

AUTUMN P. DAVIDSON, *Davis, California*

Although many bitches whelp in the home or kennel setting without difficulty, requests for veterinary participation in the field of canine obstetrics have become more common. The increased financial and emotional value of stud dogs, brood bitches, and their offspring to the dog fancier makes the preventable loss of even one neonate undesirable. Breeding colonies in academic, scientific, and industrial facilities need to maximize neonatal survival for financial and ethical reasons. Veterinary involvement in canine obstetrics has several goals: to increase neonatal viability (minimizing puppies born dead from the difficulties in the birth process), to minimize morbidity and mortality in the brood bitch, and to contribute to better survival rates of neonates during the first week of life. Neonatal survival is directly related to the quality of labor (Johnson, Smith, and Baile, 1983; Neutra, 1978; Tuter and Newman, 1975). Optimal management of whelping requires an understanding of normal labor and delivery in the bitch, as well as the clinical ability to detect and treat abnormalities in the whelping process.

Dystocia is defined as difficulty in the normal vaginal delivery of a neonate from the uterus. Dystocia must be detected in a timely fashion for medical or surgical intervention to improve outcome. In addition, the etiology of dystocia must be identified for the most appropriate therapeutic decisions to be made.

NORMAL GESTATION IN THE BITCH

Clinicians commonly are asked to ascertain if a bitch is at term pregnancy and ready chronologically to deliver a litter and to intervene if labor has not begun on time. Prolonged gestation is a form of dystocia. Normal gestation in the bitch is 56 to 58 days from the first day of diestrus (detected by serial vaginal cytologies, defined as the first day that cytology returns to 50% or fewer cornified/superficial cells) or 64 to 66 days from the initial rise in progesterone from baseline (generally >2ng/ml), which equates to the day of the luteinizing hormone (LH) surge or 58 to 72 days from the first instance that the bitch permitted breeding (Concannon, Whaley, and Lein, 1983). Predicting gestational length without prior ovulation timing is difficult because of the disparity between estrual behavior and the actual time of conception in the bitch and the length of time semen can remain viable in the bitch reproductive tract, often up to more than 7 days (Feldman and Nelson, 1996). Breeding and conception dates do not correlate closely enough to permit highly accurate prediction of whelping dates. In addition, clinical signs of term pregnancy are not specific: the radio-

graphic appearance of fetal skeletal mineralization varies at term, fetal size varies with breed and litter size, and the characteristic drop in body temperature (typically less than 100° F) may not be detected in all bitches and varies in others.

Breed, parity, and litter size also can influence gestational length (Eilts et al., 2002). Astute dog owners and clinicians may be able to detect subtle signs of impending delivery such as relaxation of the perineum, mammary engorgement, or a change in the appearance of the gravid abdomen, but these are not sensitive or specific. The inability to clinically manage prematurity in the canine effectively makes hastened intervention in the whelping process undesirable. Unfortunately an excessively conservative approach resulting in intrauterine fetal death is undesirable as well (Wallace, 1994).

Bitches typically enter stage I labor within 24 hours of a decline in serum progesterone to below 2 to 5 ng/ml (Concannon, McCann, and Temple, 1989), which occurs in conjunction with elevated circulating prostaglandins and is commonly associated with a transient drop in body temperature usually to less than 100° F. Monitoring serial progesterone levels for impending labor is problematic because in-house kits enabling rapid results are inherently inaccurate between 2 and 5 ng/ml. Commercial laboratories offering quantitative progesterone by chemiluminescence typically have a 12- to 24-hour turnaround time, which is not rapid enough to enable decisions about an immediate indication for obstetric intervention. Clearly it is beneficial to obtain information about ovulation timing, minimally by determining the onset of cytologic diestrus, for evaluating gestational length at term. If only breeding dates are available, the clinician should avoid electively delivering puppies younger than 62 gestational days, unless an indication of impending fetal demise is present. Fetal heart rate monitoring may be helpful; if fetal heart rates are consistently less than 150 beats/min, fetal stress may be present.

NORMAL LABOR AND DELIVERY

Stage I labor in the bitch normally lasts from 12 to 24 hours, during which time the uterus has myometrial contractions of increasing frequency and strength associated with cervical dilation. No abdominal effort (visible contractions) is evident during stage I labor. Bitches may exhibit changes in disposition and behavior, becoming reclusive and restless and nesting intermittently, often refusing to eat, and sometimes vomiting. Panting and trembling may occur. Vaginal discharge typically is clear and watery.

Normal stage II labor is defined to begin when external abdominal efforts can be seen accompanying myometrial contractions to culminate in the delivery of a neonate. Presentation of the fetus at the cervix triggers the Ferguson reflex, promoting the release of endogenous oxytocin from the hypothalamus. Typically these efforts should not last longer than 1 to 2 hours between puppies, although great normal variation exists. The entire delivery can take between 1 to longer than 24 hours; however, normal labor outcome is associated with shorter total delivery time and intervals between neonates (Darvelid, 1985; Gaudet, 1985; Gaudet and Kitchell, 1985). Vaginal discharge can be clear, serous to hemorrhagic, or green (uteroverdin). Typically bitches continue to nest between deliveries and may nurse and groom neonates intermittently. Anorexia, panting, and trembling are common.

Stage III labor is defined as the delivery of the placenta. Bitches typically vacillate between labor stages II and III until the delivery is complete. During normal labor all fetuses and placentae are delivered vaginally, although they may not be delivered together in every instance. Occasionally placentae are delivered hours after delivery of puppies is complete. Bitches typically consume placentae, making client counts potentially inaccurate.

DETECTING ABNORMALITIES IN CANINE LABOR

The standard approach to labor management in the bitch has involved subjective monitoring of the bitch's behavior, rectal temperature, progression of whelping, and the physical condition of the neonates. Little accurate, timely, and evidence-based information is made available to the clinician concerning actual uterine activity or prepartum fetal viability with this methodology. Telephone consultations between the veterinarian and breeder or kennel manager usually entail interpretation of indirect information such as time between deliveries, color of vaginal discharge, presence and nature of externally visible abdominal contractions, and occurrence of stillborn puppies. Although generally acceptable (associated with a favorable outcome) for the uneventful delivery in a young, healthy bitch, whelping associated with fetal and maternal morbidity and mortality is familiar to most clinicians in reproductive practice. For these cases, improved diagnostic tools are desirable, such as those used in human obstetrics. Clinical information about the onset, duration, and progression of the stages of labor, frequency and strength of myometrial contractions, progression of delivery of fetuses into the uterine body and vagina for birth, and physical status of the fetuses is helpful for obstetric decision making (Friedman, 1968). Evaluating the metabolic status of bitches presented for dystocia is important if hypocalcemia or hypoglycemia is suspected but neither is commonly detected.

Recently a system for monitoring labor and fetal viability in the bitch has become available commercially (Veterinary Perinatal Services, Inc.). This system is intended for use by veterinarians in the clinical setting when evaluating a bitch in labor or by dog fanciers or kennel managers with veterinary supervision in the home or kennel setting. The Veterinary Perinatal Service (VPS) design is based on labor monitoring systems used routinely in human obstetrics. The uterine

monitoring system consists of a tocodynamometer (sensor), a recorder, and a modem (Healthdyne Inc.; Sonicaid, Oxford Instruments) (Fig. 215-1). The uterine sensor detects changes in intrauterine and intraamniotic pressures. The sensor is strapped over a lightly clipped area of the bitch's caudolateral abdomen using an elasticized strap. The sensor's recorder is worn in a small backpack placed over the caudal shoulder area (Fig. 215-2). Bitches should be at rest in the whelping box, cage, or a crate during the monitoring sessions. The monitoring equipment is well tolerated. Subsequent to each recording session, data are transferred from the recorder to the service center using a modem with the telephone.

Fetal heart rate assessments can be performed easily by using either real-time ultrasound or a handheld Doppler unit. Normal fetal heart rates generally range above 220 beats/min. Normal beagles at term have heart rates at least twice the maternal rate. Fetal distress is evident by persistent fetal bradycardia of 120 to 150 beats/min. In a model of impaired oxygen delivery, heart rates in fetal dogs were recorded during hypoxic episodes; they showed that decelerations were an early sign of fetal hypoxia (Monheit, Stone, and Abitobol, 1988).

Fig. 215-1 Veterinary obstetrical monitoring equipment consists of a tocodynamometer (sensor, recorder, and modem, *left*) and hand-held Doppler unit (*right*).

Fig. 215-2 A monitoring session showing a pregnant Labrador retriever bitch with tocodynamometer sensor in place. The sensor is placed over a lightly clipped area of the gravid lateral abdomen.

Fetal heart rate monitoring, performed with either a real-time ultrasound probe (5 to 7.5 MHz) or a hand-held Doppler unit, is best used with bitches in lateral recumbency, using acoustic coupling gel (Fig. 215-3). Visualization of the fetal cardiac valve motion enables estimation of the heart rate with real-time ultrasound. Directing the handheld Doppler perpendicularly over a fetus results in a characteristic amplification of the fetal heart sounds, distinct from maternal arterial, digestive, or cardiac sounds, enabling audible determination of fetal heart rates. The presence of fetal distress is reflected by sustained deceleration of the heart rates. Decelerations associated with uterine contractions suggest mismatch between the size of the fetus and the birth canal or fetal malposition or malposture. Malpresentation is generally not a problem in canine deliveries. Transient accelerations occur with normal fetal movement (England and Gary, 1998; Verstegen et al., 1993; Shenker, Post, and Seiler, 1975).

THE PREPARTUM VISIT

Dog fanciers or kennel personnel can perform labor and fetal monitoring with veterinary guidance by telephone after previous demonstration of equipment in the clinic or on site. Ideally such demonstration should take place during a prepartum office visit or kennel call. After performing a physical examination of the gravid bitch, the clinician reviews labor management with the client or kennel personnel, including the use of monitoring equipment and administration of any medications, as well as whelping equipment and neonatal resuscitation. Light clipping of the hair coat over the gravid area of the lateral flanks allows proper contact later of the uterine sensor and fetal Doppler. In addition, proper technique for the subcutaneous administration of injectable drugs is taught during the prepartum consult. Calcium gluconate, 10% solution with 0.465 mEq Ca^{++} (Fujisawa Inc.), and oxytocin, 10 USP units/ml (American Pharmaceutical Partners, Inc.) can be dispensed in predrawn syringes for later use on veterinary prescription.

Specific orders (Fig. 215-4) are written for each bitch by the attending veterinarian concerning the indica-

Fig. 215-3 Evaluating fetal heart rate with a hand-held Doppler. Fetal heart rates can be detected audibly or read from the unit.

tion, frequency of administration, and dosage of medications (calcium and oxytocin) and faxed to VPS. A copy is retained for the medical record. An abdominal radiograph may be obtained at the prepartum visit to best estimate litter and relative fetal size (Eneroth et al., 1999).

CLINICAL LABOR MONITORING

Use of this monitoring equipment in a veterinary clinical setting is dictated by the presentation or referral of bitches for labor evaluation and is very helpful in making immediate assessment of the quality of labor and fetal viability. Minimal monitoring of uterine activity for 30 minutes is advised. Fetal heart rate monitoring can be performed immediately after uterine monitoring while uterine data are being sent via modem and generally takes 5 to 10 minutes, depending on the number of fetuses and skill of the operator.

For labor evaluation during whelping in the home or kennel setting, uterine and fetal monitoring should be initiated at least 1 week before the first predicted whelping date and are generally performed twice daily for 1 hour at each episode approximately 12 hours apart. This permits prospective identification of normal prelabor myometrial activity and the onset and duration of stages I and II of labor (Figs. 215-5 and 215-6). Owners should attempt to identify a heartbeat for each fetus with the Doppler unit at each monitoring session. Obstetric personnel (licensed human obstetric nurses) are available 24 hours a day at the VPS central office to receive and interpret uterine contractile recordings and subsequently communicate such findings by telephone to the attending veterinary clinician. Once a bitch enters stage I labor, the subsequent frequency of uterine and fetal monitoring is based on the recommendation of such obstetric personnel and the attending veterinarian evaluating the progression of labor and neonatal condition. Obstetric personnel generally consult by telephone with the veterinary clinician continuously during actual labor monitoring.

THERAPEUTIC INTERVENTION IN DYSTOCIA

The diagnosis of dystocia can be made objectively if uterine contractility is determined to be inappropriate (generally infrequent, weak myometrial contractions) for the stage of labor (Fig. 215-7) or if excessive fetal stress as determined by fetal heart rate monitoring is resulting from labor. Subjectively the diagnosis of dystocia can be made if stage I labor is not initiated at term, if stage I labor is longer than 24 hours without progression to stage II, if stage II labor does not produce a vaginal delivery within 1 to 4 hours, if fetal or maternal stress is excessive, if moribund or stillborn neonates are resulting, or if stage II labor does not result in the completion of deliveries in a timely manner (within 12 to 24 hours).

Dystocia results from maternal factors, fetal factors, or a combination of both. Maternal factors include uterine inertia, fluid abnormalities, and pelvic canal anomalies. Uterine inertia (i.e., failure of the uterine muscle to contract in an effective manner) can be primary or secondary. Primary

WhelpWise™ Veterinary Orders

Please circle all that apply

Client _____ Client phone _____ Date _____

Animal name _____ Breed _____ Wt. _____

1. Initiate the WhelpWise™ service. Instruct client in use of equipment. Encourage client to monitor uterine contractions twice daily, preferably 10 to 12 hours apart. At the onset of an active labor pattern, client and WhelpWise staff will determine the frequency and duration of subsequent monitor sessions.

Notify me of onset of labor: **YES NO** After hours: **YES NO**

2. In the presence of inertia as documented by the external uterine contraction monitor, begin labor augmentation per protocol. **YES NO**
Notify me before beginning medications: YES NO

3. All medication doses are based on the uterine contraction pattern, and used to treat inertia only.
Medication will not be given in the presence of a strong, regular contraction pattern

Oxytocin: _____ to _____ **UNITS** administered **Sub Q or IM** every _____ minutes (Usual dose .25 to 4 units every 30-90 minutes)**Calcium solution (10%)** _____ cc, **subcutaneously** every _____ hrs. (Usual dose: 1 ml/10 lbs BW or 4.5 kg BW min. to maintain an adequate uterine contraction pattern every 4-6 hours.)**Cleanout shot of:** _____, after deliveries are complete.**Suggested breakdown:****Oxytocin:** 2 syringes with .5 units (one half unit), 3 syringes with 1 unit, 3 syringes with 2 units, 2 syringes with 3 units. In breeds over 70 lbs: add 2 syringes with 4 units, breeds over 100 lbs: add 1 additional syringe of 5 units.**Calcium:** 1/2 cc/10 pounds drawn into 3 syringes. Example: Dog's weight 30 pounds: 3 syringes of 1.5 cc.

4. Encourage client to monitor the fetal heart rates a minimum of once a day prior to labor, and every 1-2 hours or more frequently during active labor. Notify me if decelerations or absence of fetal heart rates are noted. Recommend that the client assess the fetal heart rates prior to administration of any medication.

5. If the case being monitored is a planned cesarean section, notify me at the onset of labor.

6. Notify me of the outcomes at the conclusion of service by _____ phone _____ fax

uterine inertia is multifactorial, with genetic, mechanical, hormonal, and physical components. Bitches exhibiting primary inertia fail to proceed into an effective labor pattern, and cesarean section is indicated. Bitches exhibiting secondary inertia fail to complete expulsion of all fetuses because of exhaustion of the uterine muscle. Medical man-

agement may be successful. Clinically secondary uterine inertia is the most common maternal cause of dystocia. Abnormalities of fetal/placental fluids include hydrops, an excessive accumulation of allantoic fluid associated with each fetus, causing the fetal unit to be markedly oversized. Rarely underproduction of fetal fluids occurs, resulting in

Fig. 215-5 Normal uterine baseline recording (prelabor), no contractions evident. X-axis represents time in minutes; Y-axis strength of contraction in millimeters of Mercury.

Fig. 215-6 Normal myometrial contraction, prelabor. Note excursion off baseline during contraction with return to baseline.

Fig. 215-7 Uterine inertia: abdominal efforts (seen as vertical spikes) with no myometrial contractions evident.

dystocia caused by a lack of lubricating fluids. Disorders of the birth canal contributing to dystocia include pelvic abnormalities such as narrowing from a healed fracture or congenital disorders and vaginovulvar abnormalities such as strictures. Successful natural breedings can occur despite the presence of septate (vertical) bands in the vaginal vault. Unfortunately subsequent vaginal delivery of fetuses is usually impaired. Septate bands and strictures should be detected by the veterinarian at the time of the soundness examination before breeding and resolved if possible. Annular (circular) strictures are often detected at the time of breeding since they can interfere with the ability to attain a natural tie. These may be repaired before breeding; however, recurrence is common, and elective cesarean delivery may be less problematic. Bitches with unusually small vulvar openings may require a partial episiotomy to deliver puppies vaginally.

Fetal causes of dystocia include fetal oversize; fetal anomalies; and abnormal fetal position, presentation, or posture. Fetal oversize can occur with prolonged gestation in abnormally small litters and is the most common fetal cause of dystocia. Fetal anomalies such as anasarca and hydrocephalus (abnormalities of body fluid distribution) can cause a mismatch between the size of the birth canal and the fetus. Because both an anterior (head first) and posterior (breech) presentation are normal in the bitch, only a transverse (sideways) presentation is associated with dystocia and is rare. Puppies normally are positioned with the fetal backbone adjacent to the top surface of the uterus. Malpositioning (fetal backbone adjacent to ventral surface of uterus) can cause mild dystocia. Abnormalities of posture, normal being fully extended forelimbs (as if diving), are the second most frequent fetal cause of dystocia. Malpositioning of the head, forelimbs, or hind limbs of

the canine fetus is not readily corrected with the use of forceps, traction, or digital manipulation because of the limitations of the size of the birth canal of the bitch.

The use of uterine and fetal monitors allows the veterinary clinician to detect and monitor labor and manage dystocia medically or surgically with insight. Clinical use of the monitoring equipment should dictate subsequent medical or surgical intervention. In the home or kennel setting, the administration of medications is initiated as indicated by monitoring information and only with authorization from the attending veterinary clinician. Continued monitoring permits evaluation of the response to therapy (Fig. 215-8). Unresponsive uterine inertia, obstructive dystocia, aberrant uterine contractile patterns, or progressive fetal distress without response to medical management are indications for return to the veterinary facility for cesarean section (Davidson, 2001).

Medical management revolves around the administration of calcium gluconate and oxytocin, based on the results of monitoring. Drugs are given only after 8 to 12 hours of an established contraction pattern (stage I labor) as detected by the uterine monitor and only if inertia is detected when stage II labor is anticipated. Premature administration of drugs results in suboptimal response; for this reason prelabor monitoring permitting recognition of the onset of labor is ideal.

Generally the administration of calcium increases the strength of myometrial activity, and oxytocin increases the frequency of myometrial contractions. Interestingly, despite normocalcemia, the administration of calcium gluco-

nate usually results in improved myometrial tone. Calcium gluconate, 10%, is given when ineffective, weak uterine contractions are detected. A 10% solution of calcium gluconate can be given subcutaneously, avoiding the potential for cardiac irritability associated with intravenous administration. Calcium gluconate 10% (0.465 mEq/ml) is dosed at 1 ml/4.5 kg of body weight, generally every 4 to 6 hours.

Oxytocin is administered when uterine contractions are less frequent than expected for the stage of labor. Oxytocin given too early or too late during whelping has a minimal effect on the contractile pattern. The most effective time for dosing is when uterine inertia begins to develop, before the complete cessation of uterine contractility occurs. High doses of oxytocin saturate the receptor sites and make it ineffective as a uterotonic. Substantially lower than traditional doses of oxytocin are now known to be effective in improving the quality of myometrial contractions. Oxytocin is available at a concentration of 10 units/ml, permitting accurate small dosing. Refrigeration is not required. An initial dose of 0.25 to 0.5 units per dog administered subcutaneously is advised. Subsequent doses range from 0.50 to 2 units per dog. Higher doses of oxytocin or intravenous boluses can cause tetanic, ineffective uterine contractions that compromise fetal oxygen supply during placental compression. If fetal stress is evident (persistent bradycardia) and response to medications poor, surgical intervention is indicated. Uterine hyperstimulation with elevated baseline levels of contractility compromising placental blood supply (Fig. 215-9) or a uterine obstructive pattern also negates

Fig. 215-8 Inertia as seen in Fig. 215-7 treated with 1 unit of oxytocin subcutaneously; normal contraction pattern evident.

Fig. 215-9 Uterine hypercontractility; note minimal return to baseline.

further use of calcium gluconate or oxytocin (Lopez-Zeno et al., 1992). Use of intrapartum monitoring has been demonstrated to lead practitioners to perform cesarean section earlier in some cases of dystocia, decreasing puppy mortality in these cases.

A written summary concerning the labor pattern and response to medical intervention can ultimately be incorporated into the dog's medical record for reference in future breedings. The monitoring equipment can be leased for constant use in a busy reproductive practice for a monthly fee. Alternatively, the equipment may be leased and shipped directly to the veterinary client for use during with an individual dog during labor. Practitioner and client acceptance of the equipment once familiarity is established is generally very good.

Canine Postpartum Disorders

MICHELLE ANNE KUTZLER, *Corvallis, Oregon*

The interval from parturition to weaning, the postpartum period, is typically 6 to 8 weeks in the dog. During the postpartum period uterine remodeling of the placental sites occurs, which is histologically complete by 12 weeks after delivery. Postpartum vaginal discharge, initially dark green in color, may persist for 3 to 6 weeks, over which time fibrin and blood are voided, and the discharge changes to reddish-brown. Abnormal events arising during the postpartum period are described in the following paragraphs with a summary of recommended therapies appearing at the end of this chapter (Table 216-1).

HEMORRHAGE

Scant bleeding after parturition is normal; however, excessive bleeding may indicate uterine or vaginal parturient trauma or be evidence of an underlying coagulopathy. Vaginoscopy may be useful to identify the source of bleeding. Intravenous fluid support and blood transfusions may be needed to stabilize the patient, depending on the overall condition of the animal and the total amount of blood lost. It is important to consider when correcting blood volume deficits that the normal hematocrit in most bitches at term is 30%. Although oxytocin (0.5 to 1 unit/kg, not to exceed 20 units intramuscularly [IM]) or ergonovine maleate (15.4 mcg/kg IM) is reported to reduce the size of the uterine lumen, their efficacy for the treatment of acute postpartum hemorrhage has not been evaluated critically, and ovariohysterectomy is often indicated.

SUBINVOLUTION OF PLACENTAL SITES

Subinvolution of the placental sites (SIPS) involves the delay in the normal process of placental degeneration and endometrial reconstruction with an unclear etiopathogenesis. Instead of degenerating after parturition, trophoblast cells persist within the endometrium, preventing endometrial blood vessels from developing thromboses, resulting in persistent bleeding. In addition, trophoblast cells invade the myometrium and on rare occasions may erode through the serosa, resulting in peritonitis (Beck and McEntee, 1966).

The incidence of SIPS in postpartum bitches is 10% to 20%; generally it occurs in primiparous bitches younger than 2½ years old. The only clinical sign of SIPS is persistent serosanguineous discharge for longer than 6 weeks after delivery. However, SIPS may occur in the absence of any vaginal discharge (Al-Bassam, Thomson, and O'Donnell, 1981). A presumptive diagnosis of SIPS

is made based on the clinical history. Bitches with SIPS are afebrile and otherwise healthy, which differentiates SIPS from metritis; however, abnormalities within the bladder or vagina should also be ruled out. Abdominal palpation, contrast radiography, or ultrasonography may identify discrete, firm spheroid enlargements within the uterine horns (≈2.5 cm in diameter). Identification of multinucleated, basophilic staining trophoblast cells with highly vacuolated cytoplasm on cytologic examination of the discharge or histologic examination of a uterine biopsy provides a definitive diagnosis. A cystocentesis with urinalysis and vaginoscopic examination should rule out the urinary tract and vagina as the source of the discharge.

The clinical management of SIPS must be based on the individual patient and client. Most cases of SIPS are self-limiting, which is fortunate, since medical treatment has not proven to be effective. Administration of antibiotics, progestins, or oxytocin does not decrease the duration, amount, or character of the vaginal discharge (Dickie and Arbeiter, 1993; Smith, 1986; Schall et al., 1971). Bitches intended for future breeding should be monitored cautiously until the discharge resolves spontaneously. Monitoring includes deliberate daily observation of the bitch's general appearance by the owner and weekly vaginal cytologic examinations and complete blood cell counts to confirm the absence of metritis or anemia. However, in cases of uterine rupture or severe hemorrhage or if the patient is no longer a valuable breeding animal, ovariohysterectomy is recommended. Normal fertility has been reported in bitches following recovery from SIPS.

UTERINE PROLAPSE

Uterine prolapse is relatively uncommon in the bitch and can occur during or within a few hours after parturition, involving either one or both uterine horns. Dystocia, delivery of large litters, incomplete placental separation, advanced maternal age, and excessive relaxation of the pelvic and perineal region are considered predisposing factors. Examination reveals a firm soft-tissue mass protruding from the vagina, which should be differentiated from a vaginal prolapse or neoplasia by palpation of the cervix and clinical appearance. Patients with a uterine prolapse can quickly develop hypotensive or hemorrhagic shock, especially if the ovarian or uterine vessels have been ruptured. While stabilizing the patient, the prolapsed tissues should be covered with warm, saline-moistened towels. After gentle cleaning and copiously lubricating the tissue, manual reduction,

Table 216-1

Recommended Therapies for Canine Postpartum Disorders

Drug	Dosage	Indications	Side Effects	Additional Information
Acepromazine	0.5-2 mg/kg SQ	Agalactia	Bradycardia, hypotension	
Cabergoline	5 mcg/kg q24h PO for 5 days	Adjunctive therapy for treating mastitis or puerperal tetany to suppress lactation	None observed at this dosage	
Calcium carbonate	100 mg/kg q24h PO	To prevent recurrence of puerperal tetany	May cause gastrointestinal irritation and constipation	
Calcium gluconate (10%)	0.22-0.44 ml/kg IV (slowly)	Puerperal tetany	Bradycardia and other arrhythmias	Should be administered in conjunction with careful cardiac monitoring
Cefadroxil	22 mg/kg q12h PO	Susceptible bacterial infections in lactating bitches	May cause gastrointestinal effects in susceptible animals	Has not been observed to affect nursing pups
Ergonovine maleate	15.4 mcg/kg IM	Postpartum hemorrhage	Uterine rupture has been reported	
Oxytocin	0.5-1 unit/kg, not to exceed 20 units q4-6h IM	Postpartum hemorrhage, secondary agalactia	Uterine cramping and abdominal discomfort	Milk will let down within 2 minutes of injection
PGF-2 α (Lutalyse, UpJohn)	250 mcg/kg q24h SQ	Metritis	Hypersalivation, vomiting, diarrhea, abdominal discomfort	This dose minimizes the severity of side effects while using the least number of treatments

IM, Intramuscularly; IV, intravenously; PGF, prostaglandin F; PO, orally; SQ, subcutaneously.

with or without an episiotomy, under epidural or general anesthesia should be attempted. Manual reduction may be accomplished with a gloved finger, test tube, or syringe case. Systemic antibiotics are warranted because the risk of metritis following a uterine prolapse is high. Cefadroxil (22 mg/kg q12h orally [PO]) is recommended because it has broad-spectrum antibacterial activity and has not been observed to affect nursing pups (Bonagura, 2000, p 933). If the uterine tissue is not viable or the bitch is no longer intended for breeding, manual reduction should be followed by an ovariohysterectomy. If the uterus cannot be reduced manually, the urethra should be catheterized, and the uterus may be externally amputated. The amputation procedure involves individual ligation of the uterine arteries, transection, and oversewing of the base of the uterine body. A laparotomy should follow amputation to complete the ovariohysterectomy.

SEPTIC METRITIS

Septic metritis is an acute ascending bacterial (usually *Escherichia coli*) infection of the uterus, typically at the sites of placental attachment, occurring in the immediate postpartum period. Obstetric manipulations during a dystocia, abortion, retained fetal or placental tissue, and uterine prolapse are considered predisposing factors. Clinical signs include rectal temperature higher than 39.5°C (>103°F), dehydration and anorexia, depression, disinterest in pups and agalactia, and malodorous sanguineous vaginal discharge.

Abdominal palpation may reveal a doughy, enlarged, and painful uterus. Vaginal cytology reveals large numbers of degenerative neutrophils, bacteria, and debris. Clinical pathology often shows elevated total solids (secondary to dehydration) with immature leukocytosis; however, leukopenia can occur in severely ill bitches. Abdominal radiography with or without contrast studies, ultrasonography, or hysteroscopy may aid in identifying an underlying cause. Although not diagnostic for metritis, cranial vaginal cultures with sensitivity may be helpful in determining appropriate antibiotic therapy.

Removal of pups from the bitch and administration of intravenous fluids and broad-spectrum antibiotics are necessary for treatment of accompanying septicemia. Amikacin (5 to 10 mg/kg q12h intravenously [IV]) with cephalothin (22 mg/kg q8h IV) is recommended; however, antibiotics alone may be ineffective in treating postpartum metritis (Durfee, 1968). Uterine evacuation using prostaglandin F $_2\alpha$ tromethamine (Lutalyse, UpJohn) at a dosage of 250 mcg/kg q24h subcutaneously has been determined to minimize the occurrence of side effects while obtaining a clinical cure with the least number of treatments (Feldman and Nelson, 1996). If the patient is no longer needed for breeding, ovariohysterectomy is recommended when the patient is stable for general anesthesia. Bitches recovering from acute postpartum metritis have retained their fertility, demonstrated by normal subsequent whelpings without future postpartum complications (Durfee, 1968).

AGALACTIA

Agalactia can present as either complete failure of mammary gland development (primary) or failure of milk to letdown (secondary). Debilitating maternal illness, malnutrition, and endocrine imbalances are predisposing factors. In addition, extremely stressed bitches may have elevated adrenaline concentrations, leading to decreased pituitary release of oxytocin or entry of oxytocin into the mammary gland. Acepromazine (0.5 to 2 mg/kg subcutaneously [SQ]) promotes prolactin secretion and may improve endogenous oxytocin release. Oxytocin administered either parenterally (0.5 to 1 unit/kg, not to exceed 20 units q4-6h [SQ]) or intranasally using a nebulizing spray (Syntocinon, Sandoz) into one nostril (q6-8h) results in milk letdown within 2 minutes. In addition, efforts should be made to correct the underlying maternal condition. Pups should be offered supplemental feedings or reared as orphans if the condition persists.

SEPTIC MASTITIS

Acute septic mastitis, an ascending bacterial infection involving one or more of the mammary glands, can occur secondary to galactostasis and in the presence of unsanitary housing. Clinical signs include rectal temperature higher than 39.5°C (>103°F); dehydration and anorexia; depression; disinterest in pups and agalactia; and painful, firm, and reddened mammary glands. Expressed mammary secretions tend to be sticky and discolored (either purulent or blood tinged). Clinical pathology reveals a leukocytosis with marked immature neutrophilia. Cytologic examination of the mammary secretions may reveal bacteria, white blood cells, and erythrocytes; whereas a Gram stain may improve antibiotic selection. Bacterial culture of mammary secretions typically yields *Staphylococcus* spp., *Streptococcus* spp., and *E. coli* as causal organisms. Milk white blood cell counts have been recommended in the past for diagnosing mastitis, but this test has not been reliable because cell counts tend to differ from bitch to bitch and within glands from the same bitch (Olson and Olson, 1984).

Fig. 216-1 This 5-year-old yellow Labrador retriever bitch was 2 weeks postpartum when the owner first noticed swelling in her left hind leg (note presence of dermatitis in the medial thigh). When examined in left lateral recumbency, both pairs of mammary glands (caudal abdominal and inguinal) are swollen and erythematous. In addition, the overlying skin is necrotic in multiple areas of necrosis with evidence of abscessation.

Until culture and sensitivity results are obtained, cefadroxil (22 mg/kg q12h PO) is recommended because it has broad-spectrum antibacterial activity and has not been observed to affect nursing pups (Bonagura, 2000). Pups should be allowed to nurse because nursing may speed resolution of the disease. However, if many glands are affected or the mother is severely ill, the pups should be hand raised. If the pups are weaned, cabergoline (Dostinex, Pharmacia & Upjohn) (5 mcg/kg SID PO for 5 days) may be useful to reduce lactation and prevent further bacterial extension. Warm compresses can be applied two to three times a day along with milking out the affected glands. In cases of abscessation or gangrenous mastitis (Fig. 216-1), surgical drainage and removal of the affected mammary gland may be necessary. In these cases there is a clear line of demarcation separating the healthy tissue from the gangrenous tissue.

PUERPERAL TETANY

Puerperal tetany, also known as postpartum hypocalcemia or eclampsia, generally develops less than 28 days after delivery but can occur during late pregnancy or during parturition. In the dog puerperal tetany occurs most commonly in small-breed bitches, less frequently in medium-sized bitches, and very rarely in large-breed bitches. Other than breed, predisposing factors include young age, large litter size in relation to body weight, and diet during pregnancy. Diets high in animal protein (egg or meat) or containing cereals with phytates, a compound that binds ionized calcium, making it biologically unavailable, have also been suggested to predispose to puerperal tetany.

Puerperal tetany occurs when there is an acute decrease in ionized calcium concentration. A reduction in calcium levels increases membrane permeability in nerve cells to sodium ions, causing increased frequency of spontaneous nervous activity noticeable as muscle fasciculations. Clinical signs are related not only to the absolute decrease in ionized calcium concentrations but also to the rate and progression of its decline. The onset of clinical signs is usually rapid, and the progression of signs is predictable. Early clinical signs in dogs and cats include restlessness, whining, panting, salivation, anorexia, vomiting, and behavioral changes. As the signs progress, muscle fasciculations, stiffness, ataxia, tonic-clonic muscle spasms, hyperthermia, tachycardia, seizures, and death may ensue. Ionized serum calcium concentrations less than 0.6 to 0.8 mmol/L are definitive for diagnosing puerperal tetany (Drobatz and Casey, 2000). If ionized calcium quantification is not available, total serum calcium measurements can be used, with concentrations less than 1.625 mmol/L highly indicative of puerperal tetany. Ionized calcium concentrations are typically 30% to 50% of total calcium concentrations; however, alkalosis resulting from hypersalivation may increase the protein-bound calcium fraction, resulting in a lower net decrease in ionized calcium levels (Biddle and Macintire, 2000). In addition to measuring calcium levels, a full serum chemistry evaluation is necessary because hypoglycemia and other electrolyte disturbances may develop concurrently with puerperal tetany.

Treatment for puerperal tetany is aimed at returning ionized calcium concentrations to normal values.

This is achieved by slow intravenous administration of 10% calcium gluconate (0.22 to 0.44 ml/kg) in combination with careful cardiac auscultation or electrocardiography. The development of bradycardia and other arrhythmias during intravenous calcium administration is indicative of too-rapid replacement. Full recovery or clinical cure occurs within minutes of the intravenous treatment. Judicious administration of intravenous fluids and anticonvulsants (diazepam 1 to 5 mg IV once) is indicated for treatment of hyperthermia and seizures. The pups should be removed from the dam and hand fed a milk supplement for 12 to 24 hours to prevent a relapse. If the litter is older than 4 weeks old, they should be weaned. Lactation may be suppressed using cabergoline (Dostinex, Pharmacia & Upjohn) (5 mcg/kg SID PO for 5 days). Oral supplementation with calcium carbonate (100 mg/kg q24h) and vitamin D (10,000 to 25,000 units q24h) is also recommended to prevent a relapse. Bitches may suffer from a puerperal tetany at the next whelping. However, bitches should not be supplemented with calcium during pregnancy since this increases the likelihood of developing puerperal tetany rather than preventing its recurrence.

Nutrition in the Bitch During Pregnancy and Lactation

DAVID A. DZANIS, *Santa Clarita, California*

Gestation and lactation place some of the most rigorous nutritional demands on the bitch, especially when compared to the adult, nonreproducing animal. This should not be surprising, since she is “eating for two” (or more). A dietary deficiency or excess in one or more nutrients during this life stage can have profound effects on the ability of the bitch to conceive, whelp, and raise a healthy litter.

Successful nutritional management of the bitch during pregnancy and lactation takes more than just recommending a particular brand of dog food. Rather, considering the nutrient needs of the individual animal, assessing the qualities of the ration in meeting those needs, and feeding the ration in an appropriate manner are all critical elements. The American College of Veterinary Nutrition has developed a graphic representation to help demonstrate these basic principles (Fig. 217-1).

DETERMINING NUTRIENT REQUIREMENTS

The nutrient of greatest increased demand during pregnancy and especially lactation is energy. Since daily caloric need of a given individual is also greatly influenced by body size, breed, age, activity, and environmental conditions, perhaps the best means of expressing energy needs for pregnancy and lactation is as a proportion of the normal energy requirements of the same animal at maintenance. However, to do that one must first know what the bitch's energy needs are at maintenance.

A number of equations are used to determine maintenance energy requirements of the dog, but perhaps the most widely accepted equation is:

$$\begin{aligned} \text{Metabolizable energy (ME) (kilocalories per day)} \\ = 132 \times (\text{body weight in kilograms})^{0.75} \\ (\text{National Research Council [NRC], 1985}) \end{aligned}$$

Although equations are available that do not rely on an exponent and thus are easier to calculate, determination of metabolic body weight by this method better accounts for the great diversity in adult body size in dogs. The constant (132) in the formula was determined in dogs under laboratory conditions; thus it assumes the dog to be at a moderate activity level and in environmentally favorable conditions during most of the day. Actual maintenance requirements of a given individual may vary up to 30% either way. A mostly indoor, sedentary house pet requires less to maintain body weight, whereas an outdoor kenneled dog needs more. Breed and body size are

also factors. For example, the equation coefficient may vary from 94 for a large-sized pet dog to 175 for a highly active pet Border collie (NRC, 2006).

Because of the potentially large variation in caloric requirements, perhaps a more practical means of determining needs of an individual is simply to monitor the amount of a given food (and number of calories that amount of food delivers) needed to keep the animal in optimum body condition during prebreeding. During gestation and lactation the amount of the same food can then be adjusted by the appropriate proportion. If a more calorie-dense food is fed during these periods, the proportional increase would be modified relative to the calorie content of the old and new diets.

Regardless of the actual maintenance needs, the energy requirements for early and midgestation are approximately the same as those for maintenance (Fig. 217-2). This is because, although the fetuses are developing rapidly, they remain relatively small. Only in the last few weeks of gestation are additional calories needed for growth of the puppies and maternal tissues. Depending on the number of fetuses, total weight gain by the time of parturition should be around 15% to 25% (Case et al., 2000; Debraekeleer, Gross, and Zicker, 2000). At this time the bitch likely is consuming approximately 150% of her normal maintenance needs. Expressed differently, the increase in energy requirements above maintenance from the fourth week after mating until whelping is approximately 26 kcal of ME per kilogram of body weight per day (NRC, 2006).

Dramatic increases in energy needs are seen after the first week of lactation, even though the bitch may be approaching or even falling below her prebreeding body weight after whelping. Increased energy is needed to meet the monumental nutritional demands of milk production for the ever-growing offspring. The calorie requirement of a given individual depends on the amount of milk production, which in turn is correlated with the number of puppies. For litters of one to four puppies, milk production can be estimated at 1% of the bitch's body weight per pup, which increases the bitch's energy requirement by 24 kcal of ME per kilogram of body weight per day for each puppy in the litter (NRC, 2006). For litters larger than four, milk production and caloric needs per additional pup are approximately half of these values, and the increase in milk yield as litters exceed eight pups is negligible. Put more simply, in a bitch in peak lactation (4 weeks after whelping) with a moderate-to-large litter, energy needs three times the normal maintenance requirements

Fig. 217-1 The American College of Veterinary Nutrition Iterative Process of Nutritional Assessment requires consideration of the animal, the ration, and the feeding management (Courtesy American College of Veterinary Nutrition.)

would not be surprising. As the puppies are weaned and milk production declines, the calorie needs for lactation drop, and more energy can be directed toward reestablishing normal body weight.

In addition to calories, the needs for most other essential nutrients increase during this life stage. For example, more protein, calcium, and phosphorus are needed for proper growth and bone development of the puppies. Added intake of dietary salt also is required for normal milk production. The Association of American Feed

Control Officials (AAFCO) Dog Food Nutrient Profiles indicate for which nutrients there are increased dietary needs above maintenance of the reproducing bitch (see Appendix III). Absence of an established difference in the profiles between growth/reproduction and maintenance reflects the lack of data showing a decreased need in the adult at maintenance. Also, although the amount in the diet may appear to remain the same, the actual daily intake of a given nutrient is higher because of increased food intake.

One recent recommendation by the NRC that has not been incorporated into the AAFCO Dog Food Nutrient Profiles to date is for dietary ω -3 fatty acids, specifically of α -linolenic acid (ALA) and eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) in combination. Although dietary essentiality of these fatty acids has not been established definitively, small amounts in the diet of the bitch may be helpful in normal brain and retinal development of pups, perhaps in utero but more likely via the milk during the early neonatal period. The NRC-recommended allowance for ALA and for EPA and DHA in combination in foods for dogs in gestation and lactation is 0.08% and 0.05% dry matter, or 0.2 and 0.13 g/1000 kcal ME, respectively (NRC, 2006). Notwithstanding the lack of similar recommendations in the AAFCO Profiles, no apparent developmental abnormalities caused by ω -3 fatty acid deficiencies have been reported to date for any commercial dog food.

Eclampsia, a condition characterized by periparturient hypocalcemia in the bitch (especially during early lactation), would at first thought imply that dietary calcium requirements of late gestation have not been met, such that further supplementation is indicated. Although definitive studies on the prevention of this condition in dogs are lacking, a lesson may be drawn from what is known about milk fever, a similar condition in dairy cows. Contrary to intuition, the calcium needs of the growing fetus are relatively low, and a high dietary

Fig. 217-2 Energy needs and expected body weight changes of the bitch during gestation and lactation. (Modified from Case et al., 2000; Debraekeleer, Gross, and Zicker, 2000.)

calcium intake during gestation initiates responses to suppress calcium intestinal absorption and bone and kidney resorption in the mother. Then, when lactation ensues, the dramatic loss of calcium into the milk cannot be countered by normal metabolic responses, and the animal cannot maintain normocalcemia regardless of dietary intake of calcium at that stage. On the other hand, a low calcium intake in cattle helps ensure that bone calcium remains relatively mobile and responsive to the sudden demands of lactation. However, the syndromes in dogs and cows are different, and data are lacking to indicate that a low-calcium diet in late gestation is an effective preventive in dogs. However, it does suggest that calcium supplementation beyond that already provided in a balanced diet is imprudent at best (Case et al., 2000; Debraekeleer, Gross, and Zicker, 2000).

Although carbohydrates are not recognized as essential nutrients in the dog, some authors recommend that the diet contain a carbohydrate source (Debraekeleer, Gross, and Zicker, 2000) to mitigate the slight risk of periparturient hypoglycemia in the bitch, ensure ample glucose for the developing fetuses, and help maintain lactose levels in the milk. Except for some exclusive canned and frozen pet food products (e.g., “all beef”), most dog foods (and all dry or semi-moist foods) should contain an ample source of carbohydrates.

CHOOSING THE APPROPRIATE FOOD

An abundance of high-quality, nutritionally “complete, and balanced” commercial foods are available for feeding bitches in gestation and lactation. The flavor, form (dry versus canned), and presence or absence of a particular ingredient are not as important as the product’s substantiation of nutritional adequacy. To ensure that the product is suitable to be fed as the sole source of nutrition, the information panel on the label should bear either of the following: “(Product Name) is formulated to meet the nutritional levels established by the AAFCO Dog Food Nutrient Profiles,” or “Animal feeding tests following AAFCO procedures substantiate that (Product Name) provides complete and balanced nutrition.” If it bears the statement that it is intended “for intermittent or supplemental feeding only,” bears reference to AAFCO in a manner other than either of the previous statements, refers to an organization other than AAFCO, or bears no nutritional adequacy statement, the product should not be presumed to be nutritionally sufficient.

The first AAFCO nutritional substantiation method requires that the product contain adequate but not excessive quantities of all recognized essential nutrients compared to the AAFCO Profiles, such as amino acids, calcium, and vitamin A. These levels were established using the results of scientific studies demonstrating adequacy of a given nutrient and then adding adjustment factors to allow for differences in bioavailability of nutrients in commonly used ingredients. For the feeding trial method, a specified number of bitches must be fed the product as the sole source of nutrition (except water) from breeding through peak lactation (4 weeks after whelping). Performance is judged on acceptable maintenance of body weight compared to prebreeding, normal

hematologic and serum biochemical values, and lack of any other clinical or pathologic sign of nutritional deficiency or excess. In addition, litter size, survivability, and weight of the puppies at the end of the trial must compare favorably to animals fed a ration previously shown to be nutritionally complete and balanced.

Both the profile method and the feeding trial method have their advantages and disadvantages, and neither is perfect (Dzanis, 2003). Overall the feeding trial method is the preferred choice of substantiation. However, under current AAFCO Model Pet Food Regulations for a “product family,” a pet food deemed to be “nutritionally similar” to a tested product can bear a statement suggesting completion of animal feeding tests, even though the food actually never underwent the feeding trial. This may be particularly troublesome in light of the fact that products substantiated under the product family criteria share the disadvantages of both the profile and the feeding trial methods and hence offer the least assurance of nutritional adequacy. Some product family member labels may bear a statement that accurately reflects the fact that the product is “nutritionally similar” to a tested product; but, because of a provision in the regulations, most circumvent this statement. Rather most product family members bear the same statement allowed on the tested “lead member” products. Thus it may be impossible for the veterinarian or pet owner to know whether the particular food was tested or not solely on the basis of labeling.

The good news is that the majority of products bearing the “animal feeding tests” label statements also are formulated to meet the AAFCO Profiles but simply do not allude to that fact on the label. On the other hand, a product bearing the AAFCO Profile statement most probably has not been subject to a feeding trial. Because each method has its pros and cons, the best assurance of nutritional adequacy is if the product meets *both* criteria. If there is a question about a specific product, the manufacturer’s representative should be able to attest to and document its product family status and whether the feeding-tested product also meets the AAFCO Profiles.

Another component of the nutritional adequacy statement is that it be suitable for the intended life stage. Few if any labels bear reference to nutritional adequacy for female reproduction. Rather most cite suitability for “all life stages,” which includes the rigorous demands of gestation and lactation. It must also be noted that not all intended uses of the product may be evident from the front panel designation. Many of the higher-end “adult” foods may in fact be suitable for all life stages, as would be indicated on the information panel. This is often done to distinguish the product from the manufacturer’s “puppy” product, which is generally a bit higher in nutrient density than the adult formula. Regardless, both have been held up to the same nutritional criteria; and, although relatively more of the adult formula may need to be fed compared to the growth formula, both should perform as expected. In some cases the all-life stage “adult” formula may be more appropriate for the bitch with a propensity for excessive weight gain.

For clients who prefer to offer a raw or other home-formulated food rather than a commercial food, it must be noted that there are no regulatory requirements that a

given recipe from books, Internet websites, or elsewhere be “complete and balanced.” Although testimonials or other assurances of the suitability of a given home formulation may abound, it is highly prudent to seek the advice of a board-certified veterinary nutritionist or other professional sufficiently trained to scientifically evaluate the nutritional content of the proposed diet. Also, recipes in which ingredients are not cooked may present an increased risk of harboring potentially pathogenic organisms. To mitigate the possible risk to both animal and human health, appropriate handling and sanitary measures need to be followed.

FEEDING MANAGEMENT

Feeding management of the reproducing bitch should begin well before breeding. Difficulties in conception, parturition, and successful rearing of healthy pups may occur in a bitch that is either underconditioned or overweight. Strategies to bring the bitch to optimum weight should begin many months before expected breeding. By the time of mating, the bitch should be at a stable, if not ascending, plane of nutrition. By no means should success be assumed if the animal is on a weight loss diet at the time of breeding.

Under AAFCO Model Pet Food Regulations, feeding directions are required on all “complete and balanced” product labels, although the ranges of recommended feeding amounts are often too broad to be useful. Also, foods designated just for adult use may not have directions for the pregnant or lactating bitch. A preferred method to determine amounts to be fed is by calculating the energy needs of the animal as described previously and then comparing them to the calorie content of the diet. Voluntary calorie content label statements are allowed; but, except as required for “lite” or “less calories” products intended for weight loss, these statements rarely appear on the label. If stated, the energy content must be expressed in terms of kilocalories per kilogram of food as fed. More consumer-friendly units (e.g., kilocalories per cup or can) also may be given. If the latter information is not provided, measuring the number of cups in a known weight of food such as a 20-pound bag usually gives a more accurate estimate than trying to precisely weigh a single cup of product.

In 2005 the American College of Veterinary Nutrition proposed an amendment to the AAFCO regulations to require calorie content statements on all dog and cat food labels and to require these statements both in terms of kilocalories of ME per kilogram and kilocalories of ME per cup or can. This proposal has not been adopted by AAFCO to date. Until and unless this proposal is passed, alternative methods of determining calorie content may be necessary. If the label calorie content information is absent or incomplete, the manufacturer’s representative may be able to provide that information. Alternatively calorie content can be estimated from the guaranteed analysis values using the following formula:

$$\text{ME (kcal/kg as fed)} = ((3.5 \times \text{CP}) + (8.5 \times \text{CF}) + (3.5 \times \text{NFE})) \times 10$$

where CP = percentage of crude protein, CF = percentage of crude fat, and NFE = percentage of nitrogen-free extract (carbohydrate), which is 100 minus the sum of percentages for crude protein, crude fat, crude fiber, moisture, and ash (AAFCO, 2007). This formula tends to overestimate the true calorie content of high-fiber or poor-quality foods and underestimate that of very digestible products (NRC, 2006). A reportedly more accurate, albeit more complicated, calculation of ME has been suggested:

$$\text{Gross Energy (GE)} = (5.7 \times \text{CP}) + (9.4 \times \text{CF}) + (4.1 \times (\text{NFE} + \% \text{ crude fiber}))$$

$$\text{Percentage energy digestibility (PED)} = 91.2 - (1.43 \times (\% \text{ crude fiber/proportion dry matter}))$$

$$\text{Digestible energy (DE)} = \text{GE} \times \text{PED}/100$$

$$\text{ME} = (\text{DE} - (1.04 \times \text{CP})) \times 10 \text{ (NRC, 2006)}$$

An example of estimation of ME using both methods on the same guaranteed analysis values is found in Fig. 217-3. The NRC method does yield a higher estimate for this relatively higher-fat, lower-fiber example. As an alternative to using the NRC method, substitution of the coefficients for CP, CF, and NFE with the values 4, 9 and 4, respectively, in the previous AAFCO formula may yield more accurate results when estimating the calorie content of a higher-quality diet. Regardless, the AAFCO formula is still a good means of comparing energy content among products. Since this formula calculates energy on an as-fed basis, further conversion to dry matter (i.e., the derived value divided by the proportion of the non-moisture component of the diet) is necessary to compare among products of very different moisture contents such as a dry versus a canned or semi-moist product.

Regardless of feeding directions or previous estimates of energy needs, an individual animal may vary greatly in its true requirements. Thus careful monitoring of both body weight and body condition score, with adjustment in intake as needed to maintain optimum condition, is warranted.

No change in food, feeding amount, or frequency is usually indicated the first two thirds of gestation. A temporary drop in voluntary food consumption may be observed during estrus and in midgestation, but this is normal and does not indicate a need for adjusting the feeding management as long as body weight and condition are acceptable. Beginning about 3 weeks before expected whelping, a gradual increase in nutrient intake should be initiated. This can be done simply by increasing the amount of food offered or by switching to a more calorie-dense food. The frequency of feeding may need to be increased to accommodate the increased intake. By time of parturition, a calorie intake approximately 50% above prebreeding needs should be anticipated.

As the bitch enters peak lactation, caloric requirements may triple. If not already switched during gestation, switching the diet to a more energy-dense product generally is indicated. Offering food free choice may be necessary for the bitch to be able to consume adequate quantities throughout the day. Some degree of weight loss

Guaranteed analysis:

Crude protein	28%
Crude fat	16%
Crude fiber	3%
Moisture	10%
Ash	5%

$$62\% \text{ Nitrogen-free extract (NFE)} = 100\% - 62\% = 38\%$$

$$\text{Proportion dry matter} = (100\% - 10\%)/100\% = 0.9$$

AAFCO Method

$$\begin{array}{r} 28 \times 3.5 = 98 \\ 16 \times 8.5 = 136 \\ 38 \times 3.5 = 133 \\ \hline \text{Total} \quad 367 \end{array}$$

$$\begin{aligned} \text{Calorie content} &= 367 \times 10 = 3670 \text{ kcal ME/kg as fed} \\ &= 3670/0.9 = 4078 \text{ kcal ME/kg dry matter} \end{aligned}$$

NRC Method

$$\begin{array}{r} 28 \times 5.7 = 159.6 \\ 16 \times 9.4 = 150.4 \\ 41 \times 4.1 = 168.1 \\ \hline \text{Total} \quad 478.1 \end{array}$$

$$\begin{aligned} 91.2 - (1.43 \times 3/0.9) &= 86.4 \\ 478.1 \times 86.4/100 &= 413 \\ 413 - (1.04 \times 28) &= 384 \end{aligned}$$

$$\begin{aligned} \text{Calorie content} &= 384 \times 10 = 3840 \text{ kcal ME/kg as fed} \\ &= 3840/0.9 = 4267 \text{ kcal ME/kg dry matter} \end{aligned}$$

Fig. 217-3 Example of estimating calorie content from label guaranteed analysis values using Association of American Feed Control Officials and National Research Council formulas.

compared to prebreeding may be anticipated; but, if body weight drops more than a few percent below weight at maintenance, a more calorie-dense food should be offered. As the puppies are weaned and the bitch regains any lost weight, the amounts offered can be cut back slowly so that she is near normal food intake and body weight by the time milk production has ceased.

Assuming that the appropriate food is selected as discussed previously, no dietary supplementation should be necessary. At best supplements may do no harm, but injudicious use may create nutrient excesses. The example of calcium is given earlier. However, even something as simple as added fat to increase total caloric intake may be detrimental if it suppresses intake of the mainstay diet since it decreases intake of all other essential nutrients.

Pyometra

FRANCES O. SMITH, *Burnsville, Minnesota*

Pyometra is a disease of the uterus, literally meaning *pus in the uterus*. Similar clinical entities include mucometra and hydrometra. Pyometra typically occurs in the estrogen-primed uterus during the period of progesterone dominance (diestrus) or thereafter (anestrus). It is most commonly diagnosed in an intact bitch from 4 weeks to 4 months following an estrous cycle. Many studies highlight an increased incidence of pyometra in nulliparous bitches and in bitches over 4 years of age. Pregnancy has a sparing effect on the uterus. There is no correlation between clinical signs of false pregnancy and pyometra in the bitch.

PATHOGENESIS

In one colony of beagles the incidence of pyometra was 15.2% of bitches older than 4 years of age, with the average age of onset 9.36 ± 0.35 years (Fakuda, 2001). In a population of insured dogs in Sweden in which routine ovariectomy is disallowed, the crude 12-month incidence of pyometra over the 2-year period from 1995 through 1996 was approximately 2% in bitches under 10 years of age (Egenvall et al., 2001).

The pathogenesis of pyometra in the bitch involves estrogen stimulation followed by prolonged periods of progesterone dominance. Progesterone results in endometrial proliferation, glandular secretions, and decreased myometrial contractions. Leukocyte inhibition in the progesterone-primed uterus tends to support bacterial growth. These effects are cumulative with each estrous cycle, exacerbating the uterine pathology. Dow (1957) described four stages of cystic endometrial hyperplasia (CEH) pyometra. Type one is uncomplicated CEH; type two is CEH with infiltration of plasma cells. Type three is CEH with acute endometritis. Finally, type four is CEH with chronic endometritis.

Estrogen therapy is associated with an increased risk of pyometra in bitches from 1 to 4 years of age (Chastain, Panciera, and Waters, 1999). Use of estrogens (estradiol cypionate) for mismating in diestrus bitches is particularly dangerous and has resulted in approximately a 25% occurrence rate of pyometra (Bowen et al., 1985). Furthermore, use of estrogens in the bitch has a potential for idiosyncratic, nondose-related bone marrow suppression. The one (and only) time I used estradiol cypionate for mismating in an 18-month old golden retriever resulted in an open-cervix pyometra.

There is an increased risk for pyometra in several breeds, including the golden retriever, miniature schnauzer, Irish terrier, Saint Bernard, Airedale terrier, cavalier King Charles spaniel, rough collie, rottweiler, and Bernese

mountain dog (Chastain, Panciera, and Waters, 1999; Egenvall et al., 2001).

CLINICAL FINDINGS

The medical history of a female dog with pyometra can be nonspecific. In older bitches the client may not recognize an estrous cycle and assume that the bitch has experienced "menopause." The client may also mistake a serosanguinous vaginal discharge associated with pyometra with that of a normal estrus. Vaginal cytology assists in differentiating the prevailing hormonal events at the time of initial examination. Clinical history of bitches with pyometra often includes depression, inappetence, polydipsia, polyuria, lethargy, and abdominal enlargement—with or without vaginal discharge. Pyometra should always be in the differential diagnosis of a sick, intact bitch.

Bitches with pyometra typically are afebrile. An elevated white blood count is typical, and hyperproteinemia and hyperglobulinemia also are common. Prerenal azotemia accompanies dehydration, but urine-concentrating ability may be impaired. Cystocentesis is associated with the risk of perforation of the fluid-filled uterus and possible spillage of uterine contents into the abdomen. The most common organism isolated from the uterus or vaginal discharge of a bitch with pyometra is *Escherichia coli*. Culture and sensitivity of the vaginal discharge or of intrauterine fluid at the time of ovariectomy should be performed to guide antibiotic therapy.

The vaginal discharge in the CEH/pyometra complex may be purulent, sanguinopurulent (tomato soup), mucoid, or frankly hemorrhagic (Troxel et al., 2002). Vaginal discharge of any description should alert the clinician to include pyometra in the differential diagnosis. Other causes of vaginal discharge include vaginitis, estrus, immune-mediated thrombocytopenia (bloody discharge), anticoagulant toxicity, metritis, and subinvolution of placental sites.

Diagnosis is best accomplished with ultrasonography and/or radiography. The classic radiographic finding is a fluid-filled, tubular organ between the descending colon, which presents a sausagelike appearance. The uterus is best visualized with a lateral abdominal radiograph. Ultrasonographically a fluid-filled organ can again be identified, and uterine wall thickness and proliferative changes noted as well.

THERAPY

The treatment of choice for any aged or ill bitch or for a bitch with closed-cervix pyometra is complete

ovariohysterectomy. Medical treatment of bitches with closed-cervix pyometra may result in uterine rupture or in seepage of uterine contents into the abdomen. I do not advocate the use of medical management for any bitch with a closed-cervix pyometra. Bitches that are seriously ill should be stabilized medically with appropriate intravenous fluid therapy and broad-spectrum antibiotics before surgery. The clinician should be prepared to deal with bacteremia and endotoxemia. Disseminated intravascular coagulation is an infrequent but possible complication of pyometra.

Young bitches with breeding value and an open cervix, normal organ function, together with a compliant and reasonable owner, may be treated with prostaglandins. Prostaglandins increase myometrial contractility, encourage cervical relaxation, allow expulsion of the uterine contents, and with repeated doses result in lysis of the corpus luteum. Serum progesterone should be measured before treatment with prostaglandins.

The most frequently administered drug is prostaglandin $F_2\alpha$ ($PGF_2\alpha$) at a dose of 250mcg/kg every 12 hours subcutaneously until the uterus reduces to near normal in size, which typically takes 3 to 5 days. Therapy that requires a longer treatment period or a recurrence of fluid in the uterus signals a negative prognosis for prostaglandin treatment success. A vaginal culture should be obtained before treatment, and appropriate antibiotics administered for 3 to 4 weeks following therapy. Prostaglandins are not approved for small animal usage in the United States; thus an informed-consent form, including risks of treatment, should be obtained before therapy. Many other protocols have been published, starting with doses of $PGF_2\alpha$ as low as 50mcg/kg and gradually increasing to 250mcg/kg over the treatment period to decrease the side effects of panting, nausea, salivation, vomiting, and diarrhea—all of which are commonly seen 15 to 45 minutes after each injection. One study described the use of $PGF_2\alpha$ (150mcg/kg) in 17 bitches with pyometra administered by infusing 0.3ml/10kg of body weight into the vaginal canal one or two times daily for 4 to 12 days. Bitches received intramuscular antibiotics as well as the intravaginal infusion. Treatment was effective in 86.6% of these bitches (Gabor, Siver, and Szenci, 1999). It has been noted that cloprostenol, a prostaglandin analog, has been used successfully for treatment of open-cervix pyometra (Johnston, Kustritz, and Olson, 2001). However, I do not use cloprostenol because it is far more potent and

has great potential for accidental overdosage. Also of note are the antiprogesterins RU46534 and aglipristone, which have been used to treat open-cervix pyometra in Europe (Johnston, Kustritz, and Olson, 2001). These antiprogesterins are not available in the United States. In my opinion, prostaglandins should *never* be dispensed for client administration because of the narrow safety index and the potential for triggering asthmatic events and pregnancy loss in humans.

Bitches treated with prostaglandins may have their interestrus interval shortened slightly. The bitch should have a vaginal culture, be treated with appropriate antibiotics, and be bred to a fertile male at her next estrous cycle. Success results in conception rates of 50% to 65%. Fertility in bitches after pyometra therapy is decreased when compared to normal bitches. Failure to conceive or failure to be bred results in a high incidence of recurrence of pyometra, with recurrence rates as high as 77%. I have observed pyometra in subsequent generations of both chow-chows and English setters of young age, suggesting that there may be a familial tendency toward early development of CEH in these animals.

Vaginitis

MARGARET V. ROOT KUSTRITZ, *St. Paul, Minnesota*

Vaginitis is inflammation of the vaginal epithelium. This term is clinically inclusive of inflammation within the vaginal vault, around the urethral papilla, or in the clitoral fossa. Reported incidence of canine vaginitis is 0.7%. Vaginitis is not a clinical entity in cats.

Inflammation of the vaginal mucosa is not caused by primary bacterial infection. A primary cause of vaginal inflammation allows colonization of normal vaginal flora. The most common conditions reported to cause primary vaginal inflammation are chronic urinary tract infection and presence of vaginal anatomic anomalies. The mechanisms responsible for vaginitis secondary to vaginal anomalies include pooling of urine in the vagina and urine scald of the vaginal mucosa.

Two clinical forms of vaginitis occur. Juvenile or “puppy” vaginitis occurs in bitches before their first estrus. These young dogs present with a small amount of clear, sticky, odorless vulvar discharge that often is found incidentally at the time of physical examination before vaccination. Most bitches exhibit no clinical signs; the occasional bitch has excessive vulvar discharge and behaviors indicative of vaginal irritation such as licking of the vulva, scooting the hindquarters on the ground, or pollakiuria.

Adult-onset vaginitis may occur in spayed or intact adult female dogs but most commonly is seen in spayed bitches, perhaps because there are more spayed bitches in the North American population. These dogs present with a history of vulvar discharge varying in amount and character from scant and mucoid to copious and purulent. The vaginal discharge of vaginitis rarely is blood tinged or frankly hemorrhagic. Often these dogs exhibit other signs of disease such as licking of the vulva and positional urinary incontinence. Vaginitis and vulvar licking can occur with related conditions such as perivulvar dermatitis and atopy; clinical signs of these disorders also may be present.

On physical examination vulvar discharge may be evident in the vulvar cleft or dried and adhered to the perivulvar hair. The vulva may be swollen, and the clitoris hypertrophied if the dog has been licking at the area excessively. Some prepuberal or spayed dogs have an infantile vulva that is tucked up well within the perivulvar folds; these dogs also may have urinary incontinence, especially if they are overweight. Physical examination may reveal evidence of concurrent disease such as atopy.

To diagnose vaginitis, inflammation of the vaginal mucosa must be identified. The source of any vulvar discharge should be localized to the urinary tract, vagina, uterus (intact dogs), or uterine stump (spayed dogs). Digital vaginal examination and vaginoscopy can be

used to identify the presence of vaginal anatomic anomalies and to investigate for unusual underlying causes of inflammation such as foreign objects or vaginal masses. A vaginal cytology specimen should be collected and evaluated for cornification. Presence of cornified cells in a spayed bitch indicates that estrogen-secreting tissue is present; this dog should be evaluated further for ovarian remnant syndrome (Box 219-1).

Treatment of canine vaginitis requires identification and correction of any underlying causes of inflammation and symptomatic therapy if an underlying cause cannot be identified. Key questions that should be addressed in all cases include:

- Is the dog prepuberal?
- Is the dog postpuberal or spayed?
- Is the dog symptomatic?
- Is the dog asymptomatic?

No treatment is required for the dog with juvenile vaginitis with manifestations of disease beyond the presence of slight vulvar discharge. Empiric short-term therapy with a broad-spectrum antibiotic may be beneficial in some cases. A common antibiotic choice is amoxicillin-clavulanate (Clavamox [Pfizer Animal Health], 14 mg/kg twice daily orally [PO] for 14 days). Prepuberal bitches may benefit from estrous cycling as well since exposure to endogenous estrogen thickens the vaginal epithelium and allows enhanced movement of white blood cells into the vagina. The bitch's immune system may mature in that time as well. Anecdotal reports suggest that topical therapy of the perivulvar area and vulvar mucosa with antibiotic ointment may decrease vulvar licking and self-trauma. The majority of dogs with juvenile vaginitis undergo spontaneous resolution of the condition within months of diagnosis.

No treatment is required for the dog with adult-onset vaginitis showing no signs beyond the presence of slight vulvar discharge. A complete diagnostic workup should be performed before instituting antibiotic therapy. If urinary tract infection is present, the urine should be cultured and treated with an appropriate antibiotic. If a vaginal anomaly, secondary urine pooling, or a vaginal mass is present, surgical repair should be considered. Episioplasty (vulvoplasty) is appropriate treatment for dogs with concurrent vaginitis and perivulvar dermatitis and also may be beneficial for treatment of idiopathic adult-onset vaginitis. Medical therapy for idiopathic adult-onset vaginitis is symptomatic. It should be treated with an appropriate antibiotic based on culture and sensitivity testing for 1 month. If quantitative aerobic vaginal culture is not significant, empiric short-term therapy with a broad-spectrum antibiotic may be beneficial. A common

Box 219-1

Scheme for Diagnosis of Canine Vaginitis

- I. Verify inflammation of the vagina, vestibule, or clitoral fossa by vaginoscopy. An otoscope makes an adequate vaginoscope in practice. Also assess for presence of a vaginal anatomic anomaly, foreign object, or mass.
- II. Localize the site of vulvar discharge.
 - A. Urinary tract
 1. Urinalysis and urine culture on sample collected by cystocentesis
 - B. Uterus or uterine stump
 1. Abdominal palpation
 2. Abdominal radiographs and/or ultrasound
 - C. Vagina
 1. Vaginal cytology
 - a. Cornified: normal estrus? ovarian remnant?
 - b. Noncornified: normal for bitch not in estrus and for spayed bitch
 2. Quantitative aerobic vaginal culture; moderate-to-heavy growth of any single organism is significant; organisms most commonly identified are those of the normal vaginal flora (*Escherichia coli*, *Staphylococcus* spp., *Streptococcus* spp., *Proteus mirabilis*); sensitivity testing should be used to guide antibiotic therapy
 3. Vaginoscopy

antibiotic choice is amoxicillin-clavulanate (14mg/kg twice daily PO for 14 days). Some dogs require long-term, low-dose antibiotic therapy, as might be used for dogs with chronic cystitis. Concurrent therapy with

diethylstilbestrol (1 mg once daily PO for 5 days and then 1 mg every 3 to 4 days PO for 1 month), phenylpropanolamine (1.5 to 2 mg/kg PO twice daily), or prednisone (decreasing dose over 2 to 3 weeks) may be of benefit to some dogs. Prednisone should not be administered to bitches with urinary incontinence. Treatment with testosterone also may hasten resolution of clinical signs. Vaginal douches never have been demonstrated to be of benefit because of the unusual angulation and extreme length of the canine vagina. Anecdotal reports suggest that topical therapy of the perivulvar area and vulvar mucosa with antibiotic ointment may decrease vulvar licking and self-trauma.

Surgical Repair of Vaginal Anomalies in the Bitch

ROBERTO E. NOVO, *St. Paul, Minnesota*

A number of developmental and acquired conditions affect the canine vagina and vulva. Congenital conditions, which primarily affect younger dogs, include rectovaginal fistula; vulvar/vaginal hypoplasia; anovulvar cleft; clitoral enlargement; and vaginal septa, bands, or strictures. Acquired conditions generally affect older dogs and include vaginal neoplasia and vaginal prolapse. Some acquired conditions such as vaginal hyperplasia and perivulvar dermatitis can affect younger dogs. Invariably there is some overlap between congenital and acquired abnormalities because some acquired problems may develop secondary to abnormal anatomy of the reproductive tract. Surgery to correct these abnormalities often corrects the presenting clinical signs. These procedures may be as simple as digital breakdown of a thin vaginal band or more complex (e.g., complete vaginal ablation).

SURGICAL APPROACHES TO THE CANINE VAGINA

Most surgical procedures of the vagina (and vestibule) can be approached via a caudal episiotomy. More involved procedures may require a ventral approach, which necessitates a pubic osteotomy. With either surgical approach, strong consideration should be given to management of postoperative pain. The use of a fentanyl patch or epidural analgesia should be considered before surgery. An appropriately sized fentanyl patch (4 mcg/kg/hour in dogs) should be applied the day before surgery. Alternatively, an epidural with the use of morphine (0.1 mg/kg), bupivacaine (1 mg/kg), or a combination of both can be administered before or immediately after surgery. If epidural analgesia is elected, the surgeon should review the various techniques and dosing guidelines described in the veterinary literature.

Caudal Approach (Episiotomy)

When performing an episiotomy, the animal is placed in sternal recumbency with the pelvic limbs hanging over the end of the table. The edges of the table should be well padded to avoid trauma to the limbs. The table is tilted so the animal's head is down about 30 degrees and the vulva is at a comfortable working height. This head-down position may make ventilation of the patient more difficult, requiring assisted manual or mechanical ventilation to maintain adequate oxygenation and anesthetic plane. These patients are also at increased risk of gastric reflux/

regurgitation and subsequent aspiration. It is imperative that these animals be fasted at least 12 hours before surgery and receive H₂ blockers to decrease gastric acidity. In addition, a cuffed endotracheal tube should be used, and the pharynx should be evaluated and suctioned at the end of the procedure. A purse-string suture is placed around the anus to prevent fecal contamination of the surgical field. A piece of surgical tape marked *purse string* should be placed on the patient's head to remind the surgeon and anesthetist to remove the sutures once the procedure is finished. The vestibule and caudal vagina should be flushed with dilute Betadine solution as part of the surgical scrub. Three to four flushes of a 1:10 dilution of Betadine (Vedco Inc.) with sterile water should be used to minimize vaginal mucosal irritation.

An incision along the median raphe is made from the level of the caudodorsal aspect of the horizontal vaginal canal, descending to the dorsal commissure of the vulvar cleft. The incision is continued along the same plane of the skin incision through the vaginal musculature and mucosal layers. Placement of a flat instrument (i.e., scalpel handle) in the vestibule can be used to stabilize the tissues while the incision is made through the dorsal vestibular mucosa. Alternatively Metzenbaum scissors can be used to cut the mucosal layer. Cautery and ligation should be used for hemostasis. Hemorrhage is often associated with surgery to this region because of the increased vascularity to the vaginal tissues. Exposure is maintained with the use of self-retaining retractors (i.e., Gelpi or Weitlander retractors) or stay sutures (Fig. 220-1). A urinary catheter should be placed if there is potential for tissue manipulation around the urethra and urethral tubercle.

Closure of the episiotomy is performed in four layers: mucosa, muscular and subcutaneous tissues, and skin. A simple interrupted or continuous pattern of 3-0 monofilament absorbable suture is used for the mucosa. The muscular and subcutaneous tissues can be closed together or separately, depending on the size of the animal, using a simple continuous pattern of 3-0 or 4-0 absorbable suture. The skin edges can be closed with sutures (simple interrupted or cruciates) or surgical staples.

Ventral Approach

Fortunately the ventral approach to the canine vagina is not used often since it requires a pelvic osteotomy. This approach is often used for vaginal ablations or segmental resections of vaginal strictures. The urethra should be

Fig. 220-1 An episiotomy over the dorsal aspect of the vulva allows access to the lumen of the vestibule/vagina. Doyens placed on the edges of the incision allow for control of hemorrhage and visualization.

catheterized to aid in identification and prevent iatrogenic trauma.

A standard ventral midline approach is performed in the caudal abdomen up to the cranial pelvic rim. The urinary bladder can be manipulated aside to provide access to the vagina. The pelvic osteotomy is performed to increase the exposure to the vagina and urethra. The incision is extended caudally over the midline of the pubic symphysis. The adductor muscles are elevated laterally with periosteal elevators to expose the pubic and ischial rami. A partial or complete pelvic osteotomy can be performed, depending on the location and amount of exposure needed. A partial pelvic osteotomy involves osteotomies both through pubic rami and across the pubic symphysis at the level of the obturator foramen. A complete pelvic osteotomy through both pubic rami and ischial rami gives the greatest exposure. Once the surgeon has determined the location of the osteotomy, holes are predrilled on either side of the osteotomy site. It is much easier to drill these holes before performing the osteotomy, especially if using a hand chuck and pin. The osteotomy is performed with Gigli wire, rotating burr, sagittal saw, or bone cutters. The internal obturator muscle is elevated off the pubic symphysis on one side of the pelvis and hinged on the contralateral internal obturator muscle to expose the pelvic canal.

Alternatively an osteotomy through the pubic symphysis, separating the hemipelvis, can be performed. The flexibility of the pelvis allows the placement of retractors to separate the hemipelvis, giving exposure to the pelvic canal. Holes can be predrilled on either side of the pubic symphysis. Self-retaining retractors (i.e., Finochietto retractors) facilitate exposure (Fig. 220-2). Care must be taken not to put excessive stress on the hemipelvis, which can create a fracture or sacroiliac luxation (especially in young dogs or cats).

Closure of this approach begins with reduction of the pelvic floor, using 18- to 20-gauge cerclage wire. The predrilled holes allow for rapid and accurate alignment of

Fig. 220-2 A ventral approach to the female urogenital system via a pubic symphysis osteotomy. Finochietto retractors increase exposure and allow for visualization of the structures within the pelvic canal.

the pubic and ischial rami. The obturator and adductor muscle fascia from either side is sutured to its contralateral partner along the midline. Closure of the linea, subcutaneous, and skin is performed routinely. Because of the osteotomy, restricted activity should continue for 4 months following surgery. In small patients the pubic symphysis does not have to be replaced. Closure of the obturator and adductor muscles along the midline provides adequate support of the pelvic floor.

CONGENITAL ABNORMALITIES

Anovulvar Cleft

A cleft or trough is located between the ventral anus and dorsal vulva. This rare defect occurs as a result of inappropriate fusion of the urogenital folds and can be observed in sexually normal female dogs or with intersex disorders. The vestibular floor and clitoris are exposed, resulting in fecal contamination and hyperemia. Correction of this defect with a perineoplasty reduces infection and abrasion of the exposed mucous membranes and provides a more cosmetic appearance.

An H-shaped or inverted V-shaped incision is made along the mucocutaneous junction of the anovulvar cleft. The vestibular mucosal margin and skin edge must be separated. Interrupted sutures of an absorbable suture are used to close the vestibular mucosa and submucosa. This is followed by subcutaneous and skin sutures. Because of the proximity of the incision to the anus, the incision may become infected. The area must be kept clean until sutures are removed. Prophylactic antibiotics may be used, but they are not necessary. An Elizabethan collar is recommended to prevent self-mutilation to the incision.

Vulvar Hypoplasia

Vulvar hypoplasia occurs frequently in spayed female dogs. The vulva is small and recessed into the perineal skin folds. This condition is also referred to as a *juvenile/infantile vulva*. Dogs with juvenile vulva often present for perivulvar moist dermatitis (Fig. 220-3), which is

Fig. 220-3 Dog with vulvar excoriations secondary to self-mutilation associated with perivulvar fold dermatitis.

aggravated by retention of urine and/or feces within the folds of skin. A similar condition occurs in obese dogs when the redundant perineal skin covers the vulvar cleft. Recurrent vaginitis and urinary tract infections are common in these patients. Surgical removal of the perivulvar folds and antibiotic management help to alleviate clinical signs. In obese patients weight reduction may help alleviate the perivulvar dermatitis. However, before surgery is recommended, medical management should be instituted to decrease the inflammatory and infectious process around the vulva. Gentle cleansing of the affected area with a benzoyl peroxide shampoo and a mild topical astringent is started. The use of oral antibiotics and topical antibiotic-steroid cream can also be recommended. Once the inflammatory reaction has subsided, an episiotomy can be performed.

An episiotomy is performed to remove the excess perivulvar skinfolds and the underlying subcutaneous fat. Before surgery the perivulvar skin is plicated to determine how much skin should be removed. The goal is to remove enough skin so that the vulva is no longer recessed without creating excessive tension on the incision site. A crescent-shaped skin incision is made around the vulva, starting lateral to the ventral vulvar commissure, extending laterally and dorsally to a point about 1 cm dorsal to the dorsal vulvar commissure, and then extending ventrolaterally to the contralateral side. A second crescent-shaped incision begins and ends at the same points as the first incision; however, this incision extends wider than the first (Fig. 220-4). The perivulvar skin between the incisions is excised with Metzenbaum scissors. If uncertainty exists about how much skin to remove, the surgeon should consider starting the second incision with a narrow arch and, if the vulva is still recessed, creating a wider incision to remove more skin. This prevents unnecessary tension on the incision line.

Excessive subcutaneous fat dorsal to the vulva is removed. This is critical in obese animals. Hemorrhage is controlled with cautery and ligation. The subcutaneous tissues are closed using absorbable suture in a simple interrupted pattern. The first subcutaneous suture should be placed at the dorsal midpoint, followed by additional

sutures at the midpoints of the remaining defect. The skin is closed with simple interrupted nonabsorbable sutures. Again skin sutures are placed at 12, 9, and 3 o'clock positions to ensure a cosmetic closure.

Rectovaginal/Vestibular Fistula

This fistula is an abnormal communication between the rectum and the dorsal aspect of the vagina or vestibule. Affected dogs often have atresia ani or an imperforate anus. The dogs present because of passage of soft feces through the vulva. Severity of clinical signs varies with size of the fistula, type of diet, and presence of atresia ani. Dogs with atresia ani may have megacolon as a complicating factor. Vaginography or a barium sulfate enema can be used to demonstrate the location and size of the fistula.

Repair of this defect is twofold, involving restoration of the vaginal/vestibular lumen followed by restoration of the rectal lumen and anal orifice. Surgery is performed via a perineal approach. An incision is made between the anus (or region of the anus) and the dorsal vulvar cleft, along the median raphe. The subcutaneous tissues are bluntly dissected until the fistula is identified. A red rubber catheter placed within the fistula may aid in identification. The communications with the rectum and vagina/vestibule are ligated and resected. The rectal mucosa should be oversewn to ensure a tight seal. If the fistula is short and wide, ligation may not be possible. The stoma should be resected and then closed primarily with absorbable simple interrupted sutures. Again the defects should be oversewn. The subcutaneous tissues and skin should be closed routinely.

In the event of anal atresia, surgery must be performed to recreate a stoma between the rectum and anus (if present). The degree of anal abnormalities may vary from an imperforate anus in which a membrane remains at the level of the anus to complete anal atresia in which the anus and associated anal muscles are absent. Patients with an imperforate anus require opening of the anal canal. This can be performed by breaking down the membrane digitally, by blunt dissection, or by surgical resection of the membrane. Dogs with an imperforate anus must be evaluated carefully with a barium contrast study to differentiate the disorder from anal atresia, which may clinically appear the same. Dogs with an imperforate anus generally have normal anal function and tone. If anal atresia is present, there is minimal-to-no evidence of an anus, and on contrast radiography of the colon there is an absent section of rectum caudal to the fistula. A rectal pull-through procedure is performed, creating a new anal orifice. Because the anal musculature and innervation are absent, these animals have fecal incontinence. Muscle flaps can be attempted to increase tone to the new opening; however, results have been inconsistent.

Clitoral Hypertrophy/Os Clitoridis

Clitoral hypertrophy may occur in dogs with intersex disorders, dogs receiving anabolic steroids, or dogs with hyperadrenocorticism; however, this condition also may

Fig. 220-4 Epispioplasty for correction of a recessed juvenile vulva or for redundant perivulvar skin. **A**, Appearance of a dog with a recessed vulva. Note that the vulva is not visible under the redundant skin folds. **B**, The redundant skin is retracted to visualize the vulva. be found in normal females. Some dogs with chronic vaginitis may present with clitoral hypertrophy caused by excessive vulvar licking. The clitoris often protrudes through the vulvar cleft and may contain an os clitoridis (Fig. 220-5). These dogs generally are presented by an owner for cosmetic reasons, clitoral irritation and vestibular inflammation, or mutilation of the protruded clitoris. Treatment of hyperadrenocorticism or termination of steroid administration may cause resolution of clitoral hypertrophy. If an os clitoridis is present, clitoral enlargement may persist after gonadectomy. In cases in which the clitoris is protruding through the vulvar cleft, amputation of the clitoris is recommended. Clitoral amputation is performed by simple submucosal dissection. Dogs with intersex disorders may have significant bleeding during the dissection because of the presence of erectile tissue. Performing an episiotomy may improve visualization and assist with hemostasis.

Fig. 220-5 Dog with an os clitoridis. The end of the enlarged clitoris is extruded between the vulvar cleft.

Vaginal Band, Septa, and Stenosis

A number of vaginal and vestibular congenital abnormalities occur as a result of imperfect joining of the genital folds, genital swellings, or Müllerian ducts. These conditions may be incidental findings on a physical examination, or occasionally they cause a variety of clinical presentations. Bitches with stenosis or bands may present with clinical signs of chronic vaginitis, which may be associated with urine pooling in the anterior portion of the vagina. Other bitches may present for artificial insemination after unsuccessful attempts at natural breeding. The female and/or male may demonstrate pain when attempting to breed. Vaginal bands are also frequently associated with dogs having ectopic ureters. A digital vaginal examination may be most informative since visual inspection with speculums or otoscopes may bypass the abnormality. A vaginogram may be necessary to determine the extent and severity of the abnormality.

A persistent or imperforate hymen can be corrected with digital breakdown of the membrane. Vaginal bands or septa that cannot be corrected digitally may require an episiotomy and surgical resection (Fig. 220-6). Depending on the extent of the mucosal defect remaining after surgical removal of the band or septa, the defect can be left to heal by second intention or surgically closed using an absorbable suture in a simple continuous manner.

Vestibulovaginal stenosis is diagnosed as a palpable submucosal fibrous ring at the level of a persistent hymen. Vaginal stenosis is a region of vaginal hypoplasia, in which the lumen over a given area is narrower than the rest of the vagina or vestibule. Bitches with stenosis of the vestibulovaginal junction that exhibit clinical signs tend to respond poorly to digital and surgical attempts at dilation. If surgery is indicated, a vaginogram should be performed to determine the extent of the affected region. Three surgical techniques have been recommended for correction of these defects: T-vaginoplasty, stenosis resection, and partial/complete vaginectomy. Resection of

Fig. 220-6 Episiotomy performed for visualization of a vaginal band. A urinary catheter identifies the urethral opening at the base of the vestibulovaginal junction.

the stricture/stenosis has a better outcome than the T-vaginoplasty for complete resolution of clinical signs; however, the procedure is more difficult technically and therefore can have higher surgical complications. The T-vaginoplasty has been shown to resolve clinical signs in some dogs. Surgical recommendations vary with severity of the stenosis. Severe stenosis would most likely respond to resection and anastomosis, whereas the milder stenosis would probably respond to a less invasive T-vaginoplasty.

The T-vaginoplasty is performed via a standard episiotomy approach. A longitudinal incision is made on the dorsal aspect of the vaginal stricture, followed by a T-shaped closure to increase the vaginal diameter. However, this procedure has met with variable results. Bitches with submucosal fibrous rings may not require full-thickness incisions. These annular strictures located at the vestibulovaginal junction only require resection of the fibrous tissue through a mucosal incision. The fibrous ring is resected, and the remaining mucosal defect is closed so that none of the deeper vaginal tissues are exposed. In spayed bitches only the ventral 180 degrees of the stricture is removed in mild cases to allow adequate drainage of vaginal fluids. Positive postoperative results have been reported on the few cases in which complete resection and anastomosis of the defect were performed. This technique is technically more difficult since it requires a 360-degree dissection of the stenosis. A standard episiotomy may give the surgeon adequate visualization of the defect in the event of a small stricture or stenosis; however, if the defect is more extensive, as often occurs with vaginal stenosis, a ventral approach may be necessary. Full-thickness excisions of vaginal stenosis are always required. Two circumferential incisions are made cranial and caudal to the defect. Catheterization and protection of the urethra are critical when performing a vaginal resection and anastomosis. Ligation and cautery of superficial and muscular vessels are mandatory. Closure of the remaining defect can be performed once the stenosis is resected using absorbable suture in a simple interrupted pattern.

A complete vaginectomy is the final option for correction of vaginal stenosis in bitches that are not intended for breeding. Results with this technique seem to be very favorable. A standard episiotomy may be used in spayed bitches, whereas a ventral approach combined with a midline laparotomy may be used in intact bitches. The vagina is resected anterior to the urethral tubercle, making sure that the entire stenotic vagina is removed. A Parker-Kerr oversew or other inverting suture patterns are used to close the vagina.

ACQUIRED ABNORMALITIES

Vaginal Prolapse

Vaginal prolapse includes two very different disease processes. One process involves prolapse of edematous mucosa on the floor of the vaginal vault. This disease is also referred to as *vaginal edema* and was previously also referred to as *vaginal hyperplasia*. The second process involves a true prolapse of the vagina, in which the prolapse is circumferential and often includes the

cervix. These dogs have *true vaginal prolapse*. For ease of discussion, the terms *vaginal edema* and *true vaginal prolapse* are used when discussing the two disease processes.

Vaginal Edema/Hyperplasia

Young intact bitches in proestrus or estrus are frequently reported with this condition. Large and brachycephalic breeds are overrepresented. Normally during the follicular phase of the estrous cycle the vaginal and vestibular mucosa becomes thickened and edematous. Occasionally an exaggerated response occurs, resulting in excessive edema. The submucosal tissue edema and redundant mucosa at the floor of the vagina just cranial to the urethral tubercle can protrude through the vulvar labia as a fleshy red mass (Fig. 220-7). The exposed tissue is prone to trauma, desiccation, and self-mutilation. The urethra is not exteriorized and can be catheterized at the base of the edematous tissue. The location of the urethral tubercle helps distinguish vaginal edema from vaginal prolapse, in which the urethral opening may be exteriorized with the prolapsed vagina.

Conservative management consists of protection of the exteriorized portion of the mass with lubricants and prevention of self-mutilation with an Elizabethan collar. Vaginal edema is most commonly seen during the first estrous period and regresses spontaneously during the luteal phase. However, recurrence is common during following estrous cycles. Owners should be cautioned that the edematous tissue may also recur at parturition,

resulting in dystocia. Hormonal therapy with megestrol acetate (2 mg/kg orally daily for 7 days) or gonadotropin-releasing hormone (50 mcg intramuscularly once) may also be attempted. Owners should be advised of specific side effects of hormonal therapy.

Ovariohysterectomy is curative and should be considered to prevent recurrence. Surgical resection of the mass should be considered if the bitch is intended for breeding or if the tissues are traumatized. A standard episiotomy is performed to expose the base of the edematous tissue. The mass is lifted off of the vestibular floor, and the urethra catheterized to prevent iatrogenic trauma. A transverse elliptical incision is made around the base, and the redundant vaginal tissue is amputated. The vaginal mucosal defect is closed with absorbable suture in a simple continuous pattern, carefully avoiding the urethral orifice.

True Vaginal Prolapse

True vaginal prolapse occurs less frequently than vaginal edema and can be either partial or complete. In a complete true vaginal prolapse the cervix is exteriorized. In both cases there is a doughnut-shaped eversion of the vaginal tissues. This is differentiated from vaginal edema in that there is circumferential involvement of the vaginal mucosa and the urethral tubercle. Brachycephalic breeds in normal estrus are predisposed to vaginal prolapse.

No treatment may be necessary in cases with mild prolapse since spontaneous regression occurs during

Fig. 220-7 Hyperplasia of the vaginal floor. **A**, An episiotomy is performed to expose the base of the hyperplastic tissue. **B**, The pedunculated hyperplastic tissue is elevated, exposing the urethral opening. A urinary catheter is inserted to maintain visual recognition and protection of the urethra during resection of the hyperplastic tissue.

diestrus. More severe prolapses may require protection of exposed tissues. General anesthesia is required if attempting to replace the prolapsed mucosa. The everted tissue is cleaned with a dilute antiseptic solution or saline. If the edema is severe, manual compression or application of 50% dextrose solution to the mucosal surface may decrease its size, therefore facilitating reduction. A lubricated plastic syringe can be used to reduce the tissues. An episiotomy may be necessary to provide better exposure for reduction. Reduction can also be assisted by traction on the uterus via a ventral abdominal approach. Once the vagina is reduced, re prolapse can be minimized by suturing the uterine body or the broad ligament to the abdominal wall. A urinary catheter should be maintained until the vaginal swelling resolves.

Dogs with long-standing prolapses may have secondary necrosis, infection, or hemorrhage of the prolapsed tissues. These dogs should be evaluated and treated as necessary for hypotension and/or sepsis. Surgical resection of the devitalized tissues is indicated in these patients to prevent further sepsis and self-mutilation. An episiotomy helps with exposure and placement of a urinary catheter. A stepwise full-thickness circumferential incision is made in the vaginal wall. A section of 1 to 2 cm of the outer mucosal layer is incised, followed by resection of the inner noninverted mucosal layer. Horizontal mattress sutures are used to close the incision edges. Hemorrhage can be significant and should be controlled with cautery and ligation. This is continued circumferentially in small sections until the entire prolapsed tissue is resected.

Early-Age Neutering in the Dog and Cat

LISA M. HOWE, *College Station, Texas*

Veterinarians in the United States have typically recommended that female dogs and cats undergo ovariohysterectomy before the first estrus (prepubertal) to decrease the risk of mammary neoplasia and prevent unwanted pregnancy. Traditionally female dogs and cats not intended for breeding purposes have been neutered at approximately 6 months of age, and male dogs and cats have been neutered at approximately 6 to 9 months of age. In an attempt to address the dog and cat overpopulation problem in the United States, veterinarians have been advocating early-age neutering in which the animal is neutered as early as 6 weeks of age.

Although animal shelters often request that neuter contracts be signed at the time of pet adoption, many new owners fail to comply with the contract, even when financial reimbursement is available for the neuter surgery. One survey by the Massachusetts Society for the Prevention of Cruelty to animals reported that in 500 households with dogs and cats, 73% of dogs and 87% of cats were neutered, but nearly 20% of the neutered animals had produced at least one litter of offspring before neutering. In Texas a study examining over 43,000 dogs and cats 6 months and older reported that only 27% of dogs and 33% of cats were sterilized (Mahlow, 1999). It was estimated that if 80% of the estimated 10 million dogs and cats in Texas are sexually mature (believed to be a conservative estimate) and 71% of those are sexually intact, approximately 5.7 million dogs and cats would be capable of reproducing. Prepubertal gonadectomy performed before adoption on puppies and kittens can result in compliance rates of 100% for neutering and improved staff morale.

Scientific data regarding the ideal age at which dogs and cats should be sterilized are lacking. Thus, despite approval of the concept of early-age neutering by the American Veterinary Medical Association, American Animal Hospital Association, American College of Theriogenologists, Humane Society of the United States, American Humane Association, Association of Veterinarians for Animal Rights, Cat Fanciers Association, and numerous state veterinary associations, the concept remains controversial to many veterinarians. Studies conducted in the early to mid 1990s suggest that prepubertal gonadectomy surgery is safe in dogs and cats as young as 6 weeks of age (Aronsohn and Faggella, 1993; Faggella and Aronsohn, 1993; Faggella and Aronsohn, 1994). Studies demonstrated that the effects of early neutering on skeletal and physical development and behavior are similar to those of traditionally timed gonadectomy (Salmeri et al., 1991; Stubbs et al., 1996). More recent scientific studies

examining both short- and long-term outcomes of early-age neutering further support the safety of the procedure and have addressed concerns, including morbidity/mortality during and after surgery and urinary obstruction in male cats in greater depth.

SCIENTIFIC STUDIES

Although the anesthetic and surgical techniques of early-age neutering have been reported to be safe, veterinarians have persistently expressed concerns about the short- and long-term health risks. Concerns include increased susceptibility to infectious diseases, safety of anesthesia and surgery in young patients, bone growth abnormalities, urinary tract obstruction in male cats, penile and preputial development problems in male cats, perivulvar dermatitis in female dogs, urinary incontinence in female dogs, obesity, and adrenal tumors. Since the late 1990s numerous studies have been conducted that address many of these concerns and have demonstrated most of the concerns to be unfounded.

Infectious Diseases and Short-Term Morbidity/Mortality

In studies conducted in association with animal shelters, puppies and kittens undergoing early-age neutering were at no greater risk of infectious diseases or anesthetic or surgical complications than older animals. In one study of 1988 shelter animals undergoing neutering in association with the fourth-year student surgical teaching program of a veterinary college, 12 animals (0.6%) died or were euthanized because of severe infections of the respiratory tract or as a result of parvoviral enteritis during the 7-day post-operative period (Howe, 1997). All of the deaths were seen in the shelter with the shortest animal holding period; however, the incidence of infectious diseases did not differ among age-groups (<12, 12 to 23, and ≥ 24 weeks of age). When anesthetic and surgical complication rates were examined in that 7-day study, animals neutered at 24 weeks of age or older had a significantly higher minor complication rate than animals neutered at younger than 12 weeks of age, but the complication rate did not differ from animals neutered at 12 to 23 weeks of age. Minor complications included such problems as incisional swelling or suture reactions, scrotal swelling, mild gastrointestinal upsets, and cardiac rate and rhythm abnormalities during anesthesia. Differences in major complications were not detected among groups. In that study younger

patients did relatively better than older animals, even when immunity to infectious diseases may not have been strong or when veterinary students were performing anesthesia and delicate pediatric surgeries.

In a long-term study (48-month median follow-up) of these same animals (269 dogs) after adoption, there was an increased incidence of parvoviral enteritis in the puppies neutered at an early age (median age = 10 weeks) compared to the traditional age (median age = 52 weeks) (Howe et al., 2001). Parvoviral enteritis is common in puppies from shelter environments but uncommon in older dogs. The potential influence of anesthesia and surgery on the incidence of parvoviral enteritis in puppies that underwent gonadectomy could not be determined because comparisons with puppies that did not undergo gonadectomy were not performed. A similar long-term study (36-month median follow-up) of 263 cats showed that prepubertal gonadectomy did not result in an increased incidence of infectious diseases after adoption compared with traditional-age gonadectomy (Howe et al., 2000).

Long Bone Growth

Historically veterinarians believed that puppies and kittens neutered at young ages might have stunted growth. Several research studies have shown this concern to be unfounded and have demonstrated that neutering at both 7 weeks and 7 months of age results in delayed closure of the distal radial physis compared with intact animals. In the first it was shown in dogs that growth rates were unaffected by gonadectomy, but the growth period and final radial/ulnar length was extended in all neutered male dogs (neutered at 7 weeks and 7 months of age) and in females neutered at 7 weeks of age (Salmeri et al., 1991). Thus the dogs were not stunted in growth but actually were slightly taller as determined by radiographs. Another study in cats showed that males gonadectomized at 7 weeks or 7 months of age reached the growth plateau (the time when bone length no longer increases) on average 35% later and achieved radial length of 13% greater than intact males (Root, Johnston, and Olson, 1997). Female cats gonadectomized at 7 weeks or 7 months of age reached the growth plateau on average 18% later and achieved a 9% longer radial length compared to intact females. An earlier study in cats found that gonadectomy at both 7 weeks and 7 months of age in male and female cats delayed distal radial physeal closure by approximately 8 weeks compared to intact cats (Stubbs et al., 1996). The clinical significance of delayed closure of growth plates is not clear, and it is unknown whether it might make the growth plates more susceptible to injury. In long-term studies of 263 cats and 269 dogs examining outcome of gonadectomy performed at an early age or traditional age, no differences in the incidence of musculoskeletal problems (including fractures or hip dysplasia in dogs) was seen between groups in either species (Howe et al., 2000; Howe et al., 2001).

Urethral, Penile, and Preputial Development in Male Cats

One of the major concerns of veterinarians about performing early age neutering is that of lower urinary

tract disease (LUTD) and urethral obstruction in male cats. Numerous studies dating to the 1960s have examined this issue, and more currently both experimental and clinical studies have been conducted. Two experimental studies examining cats castrated at 7 weeks and 7 months of age compared to sexually intact cats have addressed this concern. The first study examined urethral development when cats were 1 year of age and found that urethral diameters as determined by contrast retrograde urethrography were similar between both groups of neutered cats compared to intact cats (Stubbs et al., 1993). Further, no difference in urethral dynamic function as determined by urethral pressure profiles was seen between groups. In the second study the diameter of the preprostatic and penile urethra as measured on voiding cystourethrograms when cats were 22 months of age was examined (Root et al., 1996). As with the previous study, no differences were seen in urethral diameter of male cats neutered at 7 weeks or 7 months of age compared to intact cats. Findings of these studies are consistent with findings of an older study examining the urethral diameter at three penile locations (just distal to the os penis, just proximal to the os penis, and 2 mm further proximal to the os penis) in cats castrated at 5 months of age compared to intact cats (Herron, 1972). At maturity (10 months of age) the urethral circumference of both groups of cats was the same in all locations.

In addition to experimental studies, a recent clinical study examined the effect of castration on the incidence of urinary system problems in a long-term follow-up of 263 cats neutered at an early age compared to the traditional age (Howe et al., 2000). The median follow-up was 37 months and included 108 male cats divided into two groups based on age at the time of castration: early age (median age at castration = 9 weeks; $n = 70$) and traditional age (median age at castration = 51 weeks; $n = 38$). In that study *traditional-age* cats had significantly more overall urinary tract problems (17%) compared to early-age cats (3%). Cystitis was the most common problem seen, and the incidence was significantly greater in traditional-age cats. There was no significant difference in the rate of urethral obstruction between groups, although 2/38 (5%) traditional-age cats suffered urinary obstruction, whereas 0/70 (0%) early-age cats became obstructed. The findings of this study support findings of a much older study that examined cats castrated from 3 months to 3 years compared to sexually intact cats, in which cats were fed a calculi-inducing diet for 16 months (Duch et al., 1978). No difference was noted in the obstruction rate between the castrated and intact groups; however, a trend toward a protective effect in the castrated group was noted in that there was a longer time before occurrence of obstruction in that group.

All of these studies examined together indicate that *urethral* development and diameter in male cats is not an androgen-dependent process, even though *penile* size and development is androgen dependent. Therefore it would appear that veterinarians should not be any more concerned about obstructive or nonobstructive LUTD in male cats castrated at an early age than those castrated at a traditional age.

Concerns have also been expressed about penile and preputial development in male cats castrated early. The balanopreputial fold is a fold of tissue (a continuous layer of epithelium) that connects the penis to the prepuce at birth. The separation process of the balanopreputial fold is androgen dependent and is complete at birth in some species but not until after puberty in other species. It has been suggested that prepubertal castration in cats might delay or prevent dissolution of the membrane, which may predispose to ascending urinary tract disease since these cats may not be able to fully extrude the penis for cleaning (Herron, 1971). Studies examining separation of the balanopreputial fold have reported mixed findings. In one study it was reported that at 1 year of age the penis could be fully extruded in all males, including those castrated at 7 weeks of age (Stubbs et al., 1996). Penile spines were absent in those castrated at 7 weeks of age and were atrophied in those castrated at 7 months. However, another study reported different findings on penile extrusion in cats at 22 months of age (Root et al., 1996). Of the cats neutered at 7 weeks of age, the penis could be fully extruded in 0% of cats; whereas in intact cats the penis could be fully extruded in 100% of the cats. Of the cats neutered at 7 months of age, the penis could be fully extruded in 60%. In males incapable of complete penile extrusion, only one third to two thirds of the length of the penis could be visualized. On the basis of the long-term clinical cat study, it would appear that failure of separation of the balanopreputial fold (when present) does not cause a clinical problem in cats neutered early (Howe et al., 2000). However, should cats become obstructed, penile manipulations for catheterization may be more challenging because of small penile size and potential inability to fully extrude the penis.

Genitalia Development in Dogs

The penis, os penis, and prepuce of puppies neutered at 7 weeks of age are infantile in appearance compared to those neutered at 7 months or left intact (Salmeri et al., 1991). To date there have been no published reports of an increased incidence of balanoposthitis as a result of infantile genitalia. In females vulvas of puppies neutered before puberty are small when compared to those of intact dogs (Salmeri et al., 1991). However, vulvas may also appear small in some female dogs spayed later in life or in intact females during anestrus. Perivulvar dermatitis can occur in female dogs with small or recessed vulvas, especially if the dog is fat or has excessive skin covering the vulva. To date there is no information to suggest that the incidence of perivulvar dermatitis is higher in female dogs spayed at an early age compared with those spayed at the traditional age. Regardless of the age at gonadectomy, the vulva, vestibule, and vagina undergo atrophy.

Urinary Incontinence in Female Dogs

In the female dog an increased incidence of urinary incontinence has been associated with ovariohysterectomy. Although there are many causes of urinary incontinence, hormone responsive incontinence is most frequently associated with ovariohysterectomy. Since the

onset of urinary incontinence in neutered dogs is variable and may occur in sexually intact animals, the cause of incontinence is most likely multifactorial in etiology. Currently there is no evidence to suggest that prepubertal gonadectomy potentiates the problem. In the long term (median follow-up time = 48 months) study in 269 dogs from animal shelters, urinary incontinence developed in three dogs (Howe et al., 2001). Two of these dogs were in the traditional age-group (median age at gonadectomy = 52 weeks), and one was in the early age-group (median age at gonadectomy = 10 weeks). Of these three dogs only one (traditional age-group) had a history consistent with hormone-responsive urinary incontinence. A difference was not detected between age-groups for incidence of incontinence.

Behavior

Concerns regarding potential negative behavioral consequences of prepubertal gonadectomy have been cited as a reason to avoid early neutering. One study demonstrated that of seven behavioral characteristics assessed in dogs neutered at 7 weeks or 7 months of age compared with intact dogs, only general activity and excitability differed among groups (Salmeri et al., 1991). All neutered dogs were judged to be more active than intact dogs, and dogs neutered at 7 weeks of age were judged to be more excitable than sexually intact dogs. The most common problems reported in the long-term follow-up of dogs neutered early or at a traditional age were behavioral in nature (Howe et al., 2001). Overall 32% of dogs neutered early and 34% of dogs neutered at a traditional age had at least one behavioral problem; aggressive and destructive behaviors were most common. A difference between age-groups was not detected in incidence of overall or specific behavioral problems.

In cats the effects of neutering on behavior were examined, and it was found that cats gonadectomized at 7 weeks and 7 months were more affectionate and demonstrated less intraspecies aggression than sexually intact cats (Stubbs et al., 1996). In the 3-year follow-up study of 263 cats, no difference in the incidence of behavioral problems in cats gonadectomized at an early age (median age = 9 weeks; 26% incidence) compared to those neutered at a more traditional age (median age = 51 weeks; 35% incidence) was found. The most commonly encountered behavior problems in both groups of cats included destructive behavior and inappropriate elimination.

Obesity

Both male and female cats may become obese after gonadectomy; however, no difference between cats neutered at 7 weeks and 7 months of age was identified (Stubbs et al., 1996). In both of these groups there was increased body weight and increased depth of falciform ligament compared to intact cats. A second study demonstrated lower resting metabolic rates and lower maintenance energy requirement as measured by indirect calorimetry in cats neutered at 7 weeks and 7 months compared to sexually intact cats (Root et al., 1996). The study showed that both male and female gonadectomized cats (regardless of the

age at which they are neutered) need approximately 30% fewer calories than intact cats. Another study confirmed these findings and demonstrated that the maintenance energy requirement is substantially lower for spayed female cats than for sexually intact female cats (Flynn, Hardie, and Armstrong, 1996). It was noted that sexually intact cats appeared to self-regulate food intake, whereas spayed cats tended to eat all food available.

In dogs information regarding the propensity of animals to gain weight following neutering is less clear. One study found no difference in food intake, weight gains, or back-fat depth among puppies neutered at 7 weeks or 7 months of age or left intact (Salmeri et al., 1991). However, an older retrospective study from the United Kingdom examining 8000 dogs showed that spayed female dogs were almost twice as likely to be obese as intact female dogs (Edney and Smith, 1986).

Miscellaneous

Retention in the original adoptive household and the physical status of all body systems, including integumentary, gastrointestinal, musculoskeletal, and cardiopulmonary, were examined as part of the long-term dog and cat follow-up studies (Howe et al., 2000; Howe et al., 2001). In both cats and dogs age at neutering had no effect on the rate of retention in the original adoptive household or on problems associated with any body system except the gastrointestinal tract in dogs. Dogs neutered at a traditional age had more gastrointestinal tract problems than did dogs neutered at an early age. Most of these problems were minor, and the cause of this increased incidence was undetermined.

Concerns have been expressed that puppies and kittens neutered at early ages could be at risk for developing adrenal tumors. Although these concerns have arisen from reports that adrenal tumors in ferrets were found more often in neutered animals, there is no documentation of adrenal tumors associated with prepubertal gonadectomy in cats or dogs.

ANESTHETIC AND SURGICAL TECHNIQUES AND CONSIDERATIONS

Preoperative and Operative Considerations

Anesthetic and surgical considerations for the pediatric puppy or kitten include the potential for hypothermia and hypoglycemia, the delicate nature of pediatric tissues, and a relatively small blood volume compared to that of the adult dog or cat. Hypothermia can be minimized by using circulating warm water or air blankets and by the use of warmed intravenous fluids (if used). Excessive wetting of the pediatric patient during surgical site preparation should be avoided; and the use of warmed scrub agent (chlorhexidine) and avoidance of alcohol help preserve body heat. Minimizing operative time also helps to decrease the severity of hypothermia.

Prolonged fasting of the pediatric puppy or kitten may result in hypoglycemia since hepatic glycogen stores are minimal in neonates. Food should be withheld no longer than 8 hours, with 3 to 4 hours recommended for the

youngest patients (6 to 8 weeks old). Animals should be fed a small meal within 1 to 2 hours after recovery from anesthesia.

Pediatric tissues are very friable and should be handled with care. The relatively small blood volume of pediatric puppies and kittens makes meticulous hemostasis imperative. Fortunately the small size of blood vessels and the presence of minimal abdominal and ovarian bursal fat permit excellent visualization of the vasculature and precise hemostasis.

Numerous protocols for anesthetic management of the pediatric puppy or kitten undergoing early-age neutering have been reported and typically involve balanced anesthesia techniques. Efficacious protocols include:

1. Puppies
 - a. For females: atropine (0.04 mg/kg intramuscularly [IM]) and oxymorphone (0.11 mg/kg IM), followed by propofol (3.4 mg/kg IV) 15 minutes later with isoflurane for maintenance
 - b. For males: atropine (0.04 mg/kg IM) and oxymorphone (0.22 mg/kg IM), followed by propofol (6.5 mg/kg intravenously [IV]) 15 minutes later with isoflurane if additional analgesia is needed
 - c. For males or females: glycopyrrolate (0.011 mg/kg IM) and butorphanol (0.22 mg/kg IM), followed by pentothal (22 mg/kg IV) to effect 15 minutes later with halothane or isoflurane for maintenance
2. Kittens
 - a. For females: midazolam (0.22 mg/kg IM) and ketamine (11 mg/kg IM) with isoflurane for maintenance
 - b. For males: tiletamine-zolazepam (11 mg/kg IM) followed by isoflurane if additional analgesia is needed
 - c. For males or females: glycopyrrolate (0.011 mg/kg IM), butorphanol (0.22 mg/kg IM), acepromazine (0.055 mg/kg IM), and ketamine (11 mg/kg IM) with halothane or isoflurane for maintenance

When performing early-age neutering, perioperative antimicrobial therapy is not indicated unless a preexisting bacterial skin condition is present at or near the surgical site, another medical condition necessitates antibiotic therapy, or a break in aseptic technique occurs. If necessary, intravenous cefazolin may be administered (22 mg/kg) during anesthetic induction or if a break in surgical asepsis occurs.

To prevent unnecessary abdominal exploratory surgery in the future, all puppies and kittens undergoing early-age neutering should be tattooed to identify their neutered status. The recommended tattoo site is the prepubic area in females and the inguinal area in males. The appropriate female or male gender symbol along with an encircled "X" is used to denote the neutered status. Tattooing may be performed after the surgical site has been clipped but before surgical preparation of the area.

Ovariohysterectomy

Pediatric ovariohysterectomy may be performed similarly to adult ovariohysterectomy with slight modifications. Puppy incisions are started relatively more caudal

to the umbilicus than in adult dogs. Typically the uterus is more easily exposed in puppies if the incision is started at least 2 to 3 cm caudal to the umbilicus. This placement results in the incision being nearer the middle third of the distance from the umbilicus to the cranial brim of the pelvis, similar to a cat incision. In kittens the incision is placed in a location similar to that of adult cat incisions. Substantial amounts of serous fluid may be an incidental finding in the abdominal cavity of both puppies and kittens. To improve visualization of the abdominal contents, it may be necessary to use gauze sponges to remove some of the fluid. Because of incision location in both puppies and kittens, the uterus may be located easily by looking between the urinary bladder and colon. In contrast to adult dogs and cats, it is recommended that the use of a Snook ovariohysterectomy hook be avoided in pediatric puppies and kittens because of the delicate nature of the tissues.

Uterine tissue is extremely fragile and friable in both puppies and kittens; therefore care must be used to avoid excess traction. After the uterus has been located, the suspensory ligament may be broken down carefully to improve visualization. The ovarian vessels are double ligated using 3-0 to 4-0 absorbable suture material or appropriately sized stainless steel hemostatic clips. In very small pedicles a single ligature may be sufficient to prevent hemorrhage.

After the ovarian pedicles have been ligated on both sizes, the remaining broad ligaments are broken down, and the uterus ligated at the junction of the uterine body and cervix using absorbable suture material or hemostatic clips. Once the reproductive tract has been removed, it should be examined for complete removal (of ovaries and uterine body), and the abdomen should be examined for evidence of hemorrhage. The ventral fascia (external rectus sheath) can be closed with either a simple interrupted or continuous pattern using 3-0 (or possibly 2-0 on large puppies) absorbable (polydioxanone, polyglyconate, or polyglactin 910) or monofilament nonabsorbable (polypropylene, polybutester, or nylon) suture material. It is important to differentiate the ventral fascia from overlying subcutaneous tissue, which requires careful attention, particularly in young puppies. The subcutaneous layer may be closed with an absorbable suture material (3-0 or 4-0, poliglecaprone 25 is preferred) in a continuous intradermal pattern to avoid the use of skin sutures. Some veterinarians avoid using skin sutures in pediatric puppies and kittens to prevent premature suture removal by the patient; however, I routinely use *loosely* placed skin sutures without complication.

Castration

Pediatric puppy castration is also performed with modifications to the techniques used in adult dogs. Because puppy testes are mobile and can be difficult to identify, careful palpation must be used to determine whether both testicles have descended before beginning surgery. If one or both testes have not descended, standard cryptorchidectomy techniques may be used for castration, or surgery postponed pending descent of the testicle(s) or increased patient size. The entire scrotal region is clipped and surgi-

cally prepared to permit the scrotum to be included in the surgical sterile field. Because of the small size and mobility of the puppy testicles, including the scrotum in the surgical field can facilitate locating and manipulating the testicles. Clipping and surgical preparation of the scrotum does not cause scrotal irritation in puppies as it does in adult dogs because the scrotal sac of puppies is not well developed compared to that of adult male dogs. Puppies may be castrated through a single midline prescrotal or scrotal incision or through two scrotal incisions similar to a feline castration. When a midline incision is used, the testicles must be held securely underneath the incision site to prevent iatrogenic penile trauma. Following exposure of the testicle and spermatic cords in closed fashion (testes remain enclosed in the parietal vaginal tunic during castration), the spermatic cords are ligated (double ligations preferred) with 3-0 absorbable suture material or stainless steel hemostatic clips. Adequate hemostasis should be verified before return of the pedicle to the inguinal region. Incisions may be closed using one or two buried interrupted sutures in the subcuticular layer, or incisions may be left open to heal by second-intention healing. Closure of the incision prevents postoperative contamination with urine or feces and extrusion of fat from the incision.

Kitten castration is performed using identical techniques (closed or open techniques using spermatic cord tissues for knot tying or sutures or hemostatic clips for hemostasis) as in the adult cat. Care should be used when exteriorizing and manipulating tissues to prevent rupture or tearing of the small and fragile spermatic cord. As with adult cat castrations, scrotal incisions are left open to heal by second-intention healing.

Postoperative Considerations

During the postoperative period puppies and kittens should be monitored closely for hypoglycemia, hypothermia, pain, or dysphoria. Supplemental heat, corn syrup (if dextrose-containing intravenous fluids are not used during surgery), or additional analgesics or sedatives may be used to ensure smooth recovery from anesthesia.

Pediatric patients recover much more quickly from anesthesia than older dogs and cats and may be fed a small meal 1 to 2 hours after recovery. Puppies and kittens typically are hungry at this time and are often ready to eat and play, unlike traditional-age patients undergoing gonadectomy.

Prepubertal gonadectomy of puppies and kittens (as early as 6 weeks of age) is slowly increasing in popularity in the United States as a result of mounting evidence of the safety of the procedure on both a short- and long-term basis. Puppies and kittens undergoing prepubertal gonadectomy have shorter recovery rates, lower morbidity, and similar mortality rates compared to those neutered at a more traditional age (≥ 6 months of age). Long-term outcome in cats and dogs undergoing early neutering is similar to the outcome in those undergoing traditional-age neutering. As with any surgical procedure, early-age neutering is a safe procedure when appropriate attention is paid to anesthetic and surgical techniques.

CHAPTER 222

Estrus Suppression in the Bitch

PATRICK CONCANNON, *Ithaca, New York*

During the last two decades no new methods or products for estrus prevention or suppression in small animals have been introduced in North America (Concannon, 1995a; Concannon, 1995b; Concannon and Meyers-Wallen, 1991; Concannon, 1983; Burke, 1982). This is the case despite the need for more choices in contraception to address the dog and cat overpopulation problem and despite research reports on several promising new methods. In fact, contraceptive options have decreased with the recent cessation in the manufacture and sale of the commercial liquid formulation of the androgen mibolerone (Cheque Drops, Pharmacia-Upjohn) as an estrus preventive. In North America the oral progestin megestrol acetate remains the only drug marketed for suppression of ovarian cycles, and it is only approved for use in dogs; there is no contraceptive product approved for use in cats. Options available to veteri-

narians in Europe and some Latin American countries are less limited in terms of contraceptive progestins marketed with an indication for use in small animals. These often include proligestone and medroxyprogesterone acetate (MPA) in addition to megestrol acetate (England, 1998; Concannon, 1995a; Concannon, 1995b). Furthermore, in some countries one or more progestins is marketed with an indication for use in cats, prepubertal dogs, and adult dogs, whereas in the United States megestrol acetate is sold with an indication for use in adult dogs only.

Steroid drugs marketed for human use are sometimes discovered to have been administered as contraceptive treatments in small animals by or at the request of owners; practitioners should be aware of these and their possible application and side effects. In North America these include depot MPA and various anabolic androgens, including testosterone. Annual or

semiannual administration of gonadotropin-releasing hormone (GnRH)-agonist implants can be used to suppress ovarian cycles in bitches; and the marketing of such implants with that indication in Australia, New Zealand, and Europe is expected within a few years.

The best cycle preventive measures for bitches and queens not intended for future breeding remain ovariectomy (as typically done in several European countries) or ovari hysterectomy (i.e., spaying as typically done in North America). Gonadectomy prevents subsequent uterine disease and reduces the incidence of mammary tumors in dogs, especially when performed before the first estrus (Concannon, 1995a; Concannon, 1995b; Concannon and Meyers-Wallen, 1991). Nevertheless, gonadectomy is proscribed in some countries as an unnecessary surgical insult to the animal.

STEROID CONTRACEPTIVE MECHANISM OF ACTION

Progestins

When progestins are given by serial administration or depot injection to bitches, the result is an artificial luteal phase that mimics many of the effects of the progesterone secreted during the 2-month long luteal phase that normally follows ovulation in the ovarian cycle. Likewise in cats it mimics the 20- to 40-day luteal phase that follows sterile mating or spontaneous ovulation. Many of the biologic effects of progesterone, and by extension synthetic progestins, are considered to contribute to their contraceptive action. These include an antigonadotropic action potentially resulting in lowered luteinizing hormone (LH) and follicle-stimulating hormone (FSH) concentrations; an antiestrogen action achieved by reducing the concentrations of intracellular estrogen receptors in many tissues, including those regulating gonadotropin secretion; and progestational actions on the reproductive tract occurring out of the normal sequence of the ovarian cycle, resulting in altered endometrial growth and secretion, altered cervical secretion, reduced sperm transport, and altered uterine-tube motility. In addition, progesterone and progestins can have an antiovarian effect by depressing the preovulatory surge release of gonadotropins (LH and FSH) from the pituitary, the normal stimulus for ovulation. In dogs as in many laboratory animal species, progesterone or progestin administration at or immediately after the follicular phase peak in estrogen can facilitate and advance the preovulatory LH surge and ovulation (unpublished observations). But, when administered beginning several days or more before the peak in estrogen would have occurred, progestins typically prevent the LH surge, possibly by interfering with hypothalamic and pituitary responses to estrogen.

However, none of these actions provides an explanation of how the typical clinical administration of a progestin during anestrus causes an apparent prolongation of anestrus and prevents and delays the occurrence of a new ovarian follicular phase or an associated proestrus. Long-term progestin administration in bitches not only does not lower the systemic concentrations of LH compared to those typically observed during most of normal anestrus

but may actually result in a small increase in basal LH (Colon et al., 1993; Concannon et al., 1980). Such an increase possibly may occur by partially interfering with the normal negative feedback effects of estrogen.

The negative feedback effect of progesterone during normal ovarian cycles appears to involve effects on hypothalamic neurons that regulate pulsatile GnRH release. It results in a decrease in GnRH and thus LH and FSH pulsatility and prevents the normal increase in gonadotropin pulsatility that would stimulate the next follicular phase. The same appears to be the case in dogs and probably cats subjected to contraceptive progestin treatment. The progestin prevents the increase in gonadotropin pulsatility normally required to initiate the next estrus cycle. Why in both species the effect is so prolonged following withdrawal of progestin is not understood, but it is similar to what is observed during the normal ovarian cycle, especially in dogs. In the bitch proestrus does not occur until after many weeks or months of an obligate anestrus following the end of the 7- to 10-week luteal phase and the decline in progesterone concentrations to nearly nondetectable levels (Concannon et al., 1993). Likewise in cats the 6- to 8-week luteal phase caused by a spontaneous or induced ovulation not resulting in pregnancy is followed by several weeks of anestrus and low progesterone concentrations before the next proestrus. This obligate anestrus period in dogs, cats, and other carnivores may be an evolutionary adaptation associated with being a monoes-trous and/or seasonally breeding species. In both species contraceptive progestin treatment mimics a luteal phase and postpones or reestablishes the onset of anestrus.

Androgens

The contraceptive cycle-postponing effects of androgens, like those of progesterone, appear to primarily involve a negative feedback effect at the level of the hypothalamus and possibly the pituitary. Testosterone is the natural hormone produced by the testes, is secreted by the interstitial cells nested between seminiferous tubules, and is required in high concentrations locally within the tubules for normal spermatogenesis to occur. Circulating serum testosterone in males has a negative feedback action on gonadotropin secretion, reducing both LH and FSH concentrations. The contraceptive and other effects of androgens in females may be exactly the same as in males by binding to androgen receptors or may involve cross talk with other steroid receptors. Androgen receptors have been observed in estrogen target tissues, and androgen binding can result in reduced responsiveness to estrogen. The cycle-inhibiting effect of androgens may be different from that achieved by progesterone in terms of duration of effect following hormone withdrawal. Following withdrawal, androgen therapy especially is reportedly often followed by rapid return to estrus within a few weeks, whereas progestin therapy is followed by many weeks or months of anestrus (England, 1998). However, some androgen therapy such as mibolerone typically has required 2 to 3 months for return to estrus, with a range of 1 to 7 months. In addition, termination of long-term androgen use in bitches, especially with testosterone, can also result in a

prolonged or even permanent posttreatment anestrus, as observed in some racing greyhound bitches.

SIDE EFFECTS OF CONTRACEPTIVE STEROIDS

Most, if not all, contraceptive progestins have been observed to result in both predictable and understandable side effects and less predictable and less understandable side effects. Undesirable side effects can occur from excessive dosing, prolonged exposure to lower doses, or an idiosyncratic sensitivity and responsiveness of some bitches to a particular regimen. These side effects have included uterine hyperstimulation, development of mammary tumors, and diabetes mellitus in both dogs and cats and gallbladder disease, growth hormone hypersecretion, and acromegaly in dogs (Concannon et al. 1980; Concannon, 1983). Stimulation of the endometrium can result in mucometra, cystic endometrial hyperplasia, and eventually pyometra. Uterine effects may be more pronounced when progestin is administered during or after stimulation by endogenous estrogen during proestrus and estrus or during the natural luteal phase. The occurrence of diabetes appears to involve insulin resistance possibly as a direct effect of the progestin. In dogs the insulin resistance is also related to increased serum growth hormone. Progestin-induced growth hormone secretion can result in signs of acromegaly of varying severity and appears to be related to a spontaneous phenomenon reported in older intact bitches. In the latter, natural luteal phase elevations in progesterone can result in waxing and then waning elevations in growth hormone, which in turn cause transient symptoms of acromegaly. Progestin-induced increased serum growth hormone concentrations appear to result from progestin-stimulated secretion of growth hormone by mammary tissue (Mol et al., 1996), although there is an increase in pituitary acidophils as well (El Etreby, 1979). Reduced adrenal size and reduced concentrations of cortisol also have been observed with high doses of progestin.

Side effects encountered with androgenic contraceptives are those expected for all androgens, including testosterone, and include increased muscle mass and strength, aggression, and clitoral hypertrophy. Anal gland inspissations and excessive lacrimation have been noted with at least one androgen, mibolerone (Sokolowski, 1978). Both androgens and progestins can result in masculinization of female fetuses if administered to pregnant bitches in error (Concannon and Meyers-Wallen, 1991).

PROGESTIN PRODUCTS AND APPLICATIONS

Megestrol Acetate Tablets

Megestrol acetate is marketed in North America as Ovaban tablets (Schering) for the prevention and postponement of proestrus and estrus in anestrus bitches and for the curtailment of proestrus and prevention of ovulation and estrus in early proestrus bitches. The product is marketed in bottles of 5- or 20-mg tablets for oral administration. The recommended dosage is 0.55 mg/kg/day (or 0.25 mg/

lb/day) for 32 days in anestrus bitches. Higher dosages of 2.2 mg/kg/day (or 1 mg/lb/day) for 8 days are given to bitches already in early proestrus. The indication is for use in adult bitches for up to two successive cycles, with no indication for use in cats. In some other countries, including the United Kingdom, there is an indication for the use of megestrol acetate in pubertal dogs as well as adults. In some instances there is also an indication for use in cats. Diabetes mellitus, mammary tumors, uterine disease, and liver disease are all contraindications to the use of megestrol acetate, as is pregnancy. Bitches with an unknown or ill-defined reproductive history should be confirmed to be in anestrus by vaginal cytology and progesterone assay before treatment. Administration during pregnancy can result in masculinization of female fetuses. It is recommended that treatment should not be repeated beyond two successive cycles without allowing an intervening normal cycle.

Administration during anestrus should be initiated 1 to 2 weeks or more before the next expected proestrus. If initiated too late in anestrus, a spontaneous proestrus may occur and require changing to the higher, proestrus-regimen dosing. If treatment is started immediately before the onset of proestrus, the subsequent proestrus may occur a few weeks after withdrawal. If megestrol acetate is initiated too early in anestrus, there may be no apparent postponement of the next cycle. The next proestrus typically occurs 4 to 6 months after treatment, with a range of 1 to 7 months (Burke and Reynolds, 1975). The advantages of the oral formulation are ease of administration and administration by the owner; concerns include compliance by the owner and potential for underdosing or overdosing. The bitch's body weight should be determined with exactitude, and the precise number of tablets or partial tablets of a specific formulation to be administered each day should be provided with written instructions.

Administration of megestrol acetate in early proestrus should begin within 3 days of proestrus onset. Client education as to the signs of early proestrus is important. A bitch with a normal proestrus usually lasting less than 4 days or longer than 20 days is reportedly not a good candidate for Ovaban treatment during proestrus (Harding, 1981). Early proestrus status can be confirmed by vaginal cytology showing less than 50% superficial cells, increasing rather than decreasing vulval turgidity, and serum progesterone concentrations less than 0.5 ng/ml. Proestrus treatment with megestrol acetate should be combined with isolation of the bitch from males for 3 to 8 days and until the end of serosanguineous discharge, following the recommendation of the manufacturer. The suppression of proestrus symptoms occurs by 3 to 8 days after initiation of treatment. The subsequent proestrus is expected in 4 to 6 months but ranged from 1 to 7 months in clinical trials. Administration too late in proestrus can likely result in induction of ovulation, failure to prevent ovulation, and/or the occurrence of estrus.

Megestrol acetate is currently the only cycle preventive or estrus preventive marketed for dogs in the United States and is approved for use in two successive cycles. No product is marketed for cats in the United States.

In the United Kingdom similar dosages of megestrol acetate (Ovarid, Malinckrodt Veterinary) are recommended,

including 0.5 mg/kg/day for 40 days in anestrus, 2 mg/kg/day for 8 days in early proestrus. However, when used in a pubertal proestrus, in bitches with a history of pseudopregnancy, or in bitches housed with other bitches and susceptible to pheromone effects, the recommendation has been to use a dose of 2 mg/kg for 4 days and then 0.5 mg/kg for 16 days. It is important that the onset of proestrus be accurately determined when it is used during proestrus, especially in first-cycle bitches (Bigbee and Hennessy, 1977). The treatment of anestrus bitches also includes the option to continue treating with lower doses of 0.2 mg/kg twice weekly for up to 4 months after the initial 40 days of treatment but then allowing a normal estrus to occur before retreating. Or the 40-day regimen can be followed with an early proestrus treatment at the next cycle.

In other countries generic megestrol acetate is marketed under many brand names for use in dogs and/or cats in tablets of various content (5, 10, or 20 mg), sometimes of a single content (10 mg). The 10-mg tablets can make it difficult to accurately dose smaller animals. The drug should be administered according to the manufacturer's recommendation unless there is reason to assume that a lower dose or shorter period of treatment will be effective based on recommendations of other manufacturers or review articles. Side effects in dogs most frequently mentioned by manufacturers include increased appetite and weight gain, decreased aggression, increased docility, and mammary enlargement. Megestrol acetate tablets marketed as human drugs may also be encountered (Megace, Bristol-Meyers Squibb).

Megestrol acetate at the higher proestrus dose has also been proposed and used to prevent the induction of proestrus at the onset of a treatment with a GnRH-agonist subcutaneous implant administered for long-term estrus suppression (Verstegen, Onclin, and Boisrame, 2001).

Megestrol Acetate in Cats

Ovaban is not indicated for use in cats as marketed in the United States. The drug was reported to prevent estrus in cats when administered at 5 mg/cat for 3 days followed by doses of 2.5 or 5 mg/cat once weekly, depending on size, for 10 weeks (Houdeshell and Hennessey, 1977). In the United Kingdom megestrol acetate has been marketed with an indication for long-term prevention of estrus cycles in cats, using 2.5 mg/cat weekly for up to 18 months. Presumably the drug should be initiated in interestrus or late in seasonal anestrus in preference to treating in proestrus or estrus to reduce the risk of uterine complications. Potential side effects include uterine disease; diabetes; adrenal suppression; and mammary complications, including mammary enlargement and mammary tumors. In countries where its use in cats is extralabel, a signed release should be obtained.

Medroxyprogesterone Acetate Injections

A depot injectable formulation of MPA was marketed as a dog contraceptive (Promone) in North America several decades ago but was removed from the market because of a high incidence of uterine disease. Currently an injectable

depot formulation of MPA is marketed as a human contraceptive product (Depo-Provera) and has been administered to bitches by owners and in animals imported from Europe. Injectable depot MPA is widely marketed as a veterinary drug in Europe and other locales under several trade names (Promone-E, Pharmacia-Upjohn; Perlutex Injection, Leo Laboratories; Supprestal, Vetoquinol) with an indication for prevention of ovarian cycles in bitches during anestrus and/or in cats. Various regimens for dosage and injection intervals have been recommended for bitches; they include 2.5 to 3 mg/kg every 5 months and 50 mg/bitch every 6 months. Side effects appear to be dose dependent, and dosing on a body-weight basis would be more appropriate than dosing on a per animal basis. Published dose-response studies in dogs have typically involved nonclinical, high doses in comparison to doses assumed to be near the minimal effective dose, as part of toxicity testing for human use. Side effects commonly seen with the higher doses or long-term treatment with lower doses include cystic endometrial hyperplasia, pyometra, acromegaly, gallbladder calculi and mucosal hyperplasia, and mammary tumors (Concannon et al., 1980). The mammary tumors were mostly benign, but adenocarcinomas have been observed. Development of diabetes also has been reported. Injection doses considered to be near the minimal effective dose and clinically more appropriate than higher doses are 2 mg/kg every 3 months and 2.5 mg/kg every 5 months. MPA has also been used in cats. Side effects in cats include an increased incidence of mammary adenocarcinoma (Hernandez, Fernandez, and Gage, 1975) and diabetes. An MPA dose that has been used in cats is 2 mg/kg injected every 5 months. If used in dogs, depot MPA should only be administered during confirmed anestrus. Administration during midproestrus or late proestrus (or early estrus) can result in ovulation, in pregnancy and possibly failure of parturition, in pyometra, or in pseudopregnancy. Directions by some marketers of MPA to treat animals are based on a single dose per animal or on doses for a limited number of body-weight ranges and should be replaced by doses based on body weight. Directions to use doses greater than those mentioned previously likewise would seem inappropriate, although there is some anecdotal evidence that the same progestin from different manufacturers may have different biopotencies per unit of product weight.

Proligestone Injections

Proligestone is available as a depot injectable progestin in Europe (Delvosteron, Intervet; Covinan, Intervet) and some other locations, with indications for estrus prevention in female dogs, cats, and ferrets. It is not marketed in North America. Doses of 10 to 33 mg/kg, varying inversely with body weight and including 17.5 mg/kg for 20-kg dogs and 10 mg/kg/day for all bitches 60 kg and larger, are given to bitches at 0, 3 and 7 months of treatment and subsequently at 5-month intervals. There is also an indication for its administration during proestrus to prevent ovulation and estrus. Initial studies suggested that proligestone treatment need not be restricted to any stage of the cycle and did not increase the incidence of mammary tumors or uterine disease (Concannon, 1995a; Hegstad

and Johnston, 1989). However, more recently various reports and anecdotal evidence have suggested that uterine disease, including pyometra, mammary tumors, and acromegaly, may be side effects of proligestone, as with other progestins, and that administration is best initiated during anestrus with an appreciation of potential occurrences of side effects similar to those observed with other progestins (Mol et al., 1996; Knottenbelt and Herrtage, 2002).

Other Progestin Formulations

Oral formulations of MPA are marketed as human drugs in the United States (Provera, Pharmacia Upjohn; Farlutal, Pharmacia Upjohn) and also as veterinary drugs in other countries (Perlutex Vet Tablets, Leo Laboratories). Oral MPA is marketed in the United Kingdom with an indication for use in cats (Perlutex). A suggested dosing regimen in dogs is reported to be 10 mg/bitch for 4 days and then 5 mg/bitch for 12 days, doubling the doses for bitches weighing over 15 kg (England, 1998). As with any drug, dosing on a body-weight basis could more appropriately be done by providing a dose per kilogram of body weight or by providing doses for five different body-weight ranges.

Steroid Implants

Subcutaneous Silastic (Dow Corning) implants that release a progestin have been used experimentally, especially for the contraception of exotic carnivores in zoos. Such implants can have a functional life of up to several years. Steroids that have been incorporated into such implants have included progesterone, melengestrol acetate, megestrol acetate, and levonorgestrel (Baldwin et al., 1994; Concannon, 1995; Concannon and Meyers-Wallen, 1991). None are marketed commercially. Recently a Silastic implant formulated to steadily release natural progesterone in low doses was reported to have contraceptive efficacy without side effects in small and large domestic bitches and in cats over a 4-year treatment period, with treatment initiated during anestrus in all cases (Verstegen Onclin, and Boisrame, 2004). However, plans for commercial development have not been reported.

ANDROGEN PRODUCTS

Natural androgens, including testosterone, and synthetic androgens are by definition all masculinizing and anabolic steroids, and effects are dose dependent. None are marketed with an indication for prevention of ovarian cycles in small animals in the United States, and none can be considered to be recommended or appropriate. Several are marketed in Europe and elsewhere with such indications.

Mibolerone

The androgen mibolerone, a specific androgen receptor agonist, until recently was marketed in the United States for cycle prevention in dogs (Concannon and Meyers-

Wallen, 1991). The liquid formulation for oral administration was recommended at a dosage of 30, 60, 120 or 180 mcg/day continuously for up to 2 years, with the dose depending on body weight (<12, 12 to 23, 23 to 45, or <45 kg, respectively) and all Alsatians or Alsatian-derived bitches receiving the highest dosage (Sokolowski, 1978). Administration initiated later than 1 month before the next expected estrus could result in failure to prevent proestrus. It was never marketed for use in cats because of potential effects on the clitoris, liver, and thyroid. Mibolerone is no longer marketed for veterinary use in North America, presumably because it has been implicated frequently as a drug abused by athletes to enhance strength. Like all androgens, mibolerone has anabolic effects on skeletal muscle and also had become a favored contraceptive regimen in working dogs and racing sled dogs. It is listed as a Controlled Substance in the legislation of several states.

Mibolerone liquid (100 mcg/ml) for oral administration is available from some veterinary compounding pharmacies at a cost approximating \$100 per 5000 to 60,000 mcg, making the cost not unreasonable for small and medium-sized bitches. Consideration should be given to confirmation of anestrus status before treatment initiation, potential masculinization of fetuses in pregnant bitches, possible increased incidence in ovarian fibromas with long-term use, and potential for anal gland inspissation with overdosage. Another extralabel use of mibolerone is to postpone estrus briefly (i.e., for 3 to 6 months in bitches with a history of abnormally short estrus cycles).

Testosterone

Testosterone in various chemical states and formulations and several other androgens are marketed as anabolic steroids for use in human geriatric, surgical, and anemia patients, among others, and are also subject to abuse. Testosterone particularly has been used by animal owners to effect cycle prevention and contraception in dogs used in sporting events, including sled dogs and racing greyhounds. In greyhounds weekly intramuscular injections of testosterone propionate at 110 mg/dog have been used to prevent ovarian cycles (Gannon, 1976). Oral administration of 25 mg of methyl testosterone once weekly for up to 5 years has also been used in greyhounds (Burke, 1982). Masculinizing and anabolic side effects are common. Permanent or prolonged anestrus may be a complication after treatment. The extent to which anabolic steroids are used in sporting dogs is not known. Androgen use should be considered as a possible complication in racing bitches with clitoral hypertrophy or anal gland inspissation.

In Europe available androgen products used for pet contraception include methyl testosterone and mesterolone tablets for oral administration and injectable solutions of testosterone propionate, testosterone phenylpropionate, and mixtures of testosterone esters. As England (1998) reviewed, the most common use of androgens as a cycle preventive administered during anestrus is the depot injection of mixed testosterone esters (25 mg/kg), typically every 4 to 6 weeks, often supplemented with oral dosages of methyl testosterone at 0.25 to 0.50 mg/kg.

GONADOTROPIN-RELEASING HORMONE-AGONIST IMPLANTS

GnRH-agonist (deslorelin)-releasing implants that result in the down-regulation of LH and FSH secretion and suppression of gonadal function in male dogs are currently marketed in Australia and New Zealand for use in male dogs only and are scheduled for marketing in Europe in the near future. The GnRH agonist in the circulation binds to GnRH receptors on the pituitary cells and, after an initial transient phase of stimulation of LH and FSH release, the agonist down-regulates gonadotrope cell function and chronically prevents release of gonadotropins in amounts needed to support normal gonadal function.

The application of this same technology for chronic contraception in female dogs and cats is likely to see approval in some countries within the next few years. Continuous treatment with down-regulating (i.e., desensitizing) doses of a GnRH-agonist initiated in young (3.5 to 5 months) prepubertal bitches has been shown to be 100% effective in suppressing ovarian cycles throughout treatments of 1 year and longer. It is without any obvious side effects and allows for a return to a normal puberty (albeit at an adult age) and fertility following implant removal (Rubion et al., 2006; Trigg et al., 2001; Vickery et al., 1989; Concannon, Montanez, and Frank, 1988). In adult bitches and in prepubertal bitches 7 months of age or older, the same treatment is equally effective long term and likewise reversible, except that there is typically an initial ovarian-stimulation response that often results in a proestrus and estrus during the first 2 weeks after treatment onset. The induced cycle involves increased estrogen secretion in response to the initial stimulation of LH and FSH release and can result in a spontaneous ovulation-inducing LH surge and fertile ovulation. However, pregnancies that result from breeding at the induced estrus typically fail to proceed much beyond implantation because of abnormal luteal function that occurs during continued GnRH-agonist administration. Interestingly, the same technology, with discontinuation of treatment following estrus induction and mating in adult bitches, has been used experimentally to synchronize pregnancies and treat prolonged anestrus in research dogs.

Clinical trials on two commercial long-term GnRH-agonist implant formulations in female dogs are being conducted in the expectation of gaining marketing approval for estrus suppression in bitches. These products include (1) a revised formulation of the biodegradable deslorelin-releasing implant currently marketed for male dogs in Australia (Suprelorin, Peptech Animal Health), and (2) a nonbiodegradable azagly-nafarelin releasing implant (Gonazon CR, Intervet). Single Gonazon implants administered once to prepubertal bitches at 4 to 5 months of age prevented puberty throughout the 12-month treatment, and normal estrus occurred at variable times following implant removal. Such products are likely to gain marketing approval for use in bitches in several countries because of the lack of side effects and the large margin of safety shown for these and a variety of other GnRH-agonists developed for human use. Interestingly, Gonazon-induced suppression of puberty and the resulting delay in puberty onset to 18 months of age and older had no effect

on growth or body weight measured at 22 months of age when compared to untreated control bitches (Rubion et al., 2006). The investigators speculate that perhaps weight gains sometimes associated with surgical spaying are less likely to occur with the GnRH-agonist mode of contraception.

The undesirable GnRH-agonist side effect of estrus induction in adult bitches is typically not seen when bitches are treated during early or midmetestrus (diestrus) and when progesterone is above 5 ng/ml. Some reports suggest that the estrus induction effect can be suppressed or inhibited by pretreatment with megestrol acetate at 2 mg/kg but not 1 mg/kg daily for 2 weeks (but not 1 week) before and 1 week after initiation of agonist treatment (Verstegen, Onclin, and Boisrame, 2001).

THE FUTURE OF SMALL ANIMAL CONTRACEPTION

Advances in methods to terminate pregnancy, including the use of progesterone antagonists and moderate doses of prostaglandin $F_{2\alpha}$ in combination with moderate doses of dopamine agonists have occurred within the last several years. Similar advances in the clinically applicable use of new drugs or technologies for long-term or permanent inhibition of ovarian cycles have not emerged except for the previously mentioned use of GnRH-agonist implants for suppressing LH and FSH secretion and thereby preventing recurrence of ovarian cycles. Nevertheless, several alternative technologies are being tested currently, including immunization against GnRH (Singh, 1985; Jung et al., 2005) or ovarian zona pellucida proteins (Srivastava et al., 2002; Mahi-Brown et al., 1985) and the administration of GnRH (or other reproductive hormones) conjugated to cytotoxins and thus targeting the destruction of pituitary gonadotroph cells (or other cell types) as cells required for normal cycles and/or fertility (Qi et al., 2004).

In the near term in the United States the only option for pharmacologic prevention of ovarian cycles in small animals while following the indicated use of the approved product(s) involves the oral administration of megestrol acetate to bitches in doses and durations appropriate for either anestrus bitches or for bitches already in proestrus. The use of megestrol acetate in cats, as indicated for some European formulations of the same drug, is an extralabel use in North America and should only be done in conjunction with a release-and-consent document signed by the cat owner. In other countries there can often be a greater choice, including one or more depot injectable progestins, one or more oral formulations with indications and dosages recommended for both dogs and cats, and in the near future GnRH-agonist-releasing implants for use in female and male dogs and cats. However, in cases involving steroids the veterinary practitioner should determine the time of the cycle for administration and calculate the appropriate dose on a body-weight basis by using all information available from the research and review literature and from other manufacturers. The use of cycle-suppressing hormone therapy should be proposed only for animals intended for breeding within 1 to 3 years. Animals not intended for breeding are best managed by surgical sterilization.

Canine Pregnancy Termination

BRUCE E. EILTS, *Baton Rouge, Louisiana*

If a perfect pregnancy termination drug existed, it could be given at any stage of estrus or pregnancy, it would be 100% effective, it would cause no vaginal discharge, it would have no side effects, it would not impair future fertility, it would be readily available, and it would be inexpensive. Unfortunately such a drug does not yet exist. In cases in which the bitch is not a valuable breeding animal the client should be counseled that the best option to terminate the pregnancy and prevent future pregnancies is ovariohysterectomy. The drugs available for pregnancy terminations are discussed under the general categories of those that can be used during estrus and those that can be used after pregnancy is confirmed. A comprehensive list of drugs to terminate pregnancy is not presented; however, the drugs most commonly available in the United States are discussed.

DRUGS USED DURING ESTRUS

The only drugs available to terminate pregnancy during estrus are the estrogens. The action of estrogens is not completely known; however, it is believed that they block ova transport or prevent implantation. The use of estrogens for mismatch management is cited in many texts and by many academicians as being unsafe to the extent of being malpractice; however, little published data substantiate these statements. Estrogens should be used only during estrus because their use during diestrus significantly increases the chance of inducing a pyometra. A vaginal cytology examination having 90% to 100% cornified cells shows that the bitch is truly in estrus; whereas, if the cells are not cornified, the bitch is not in estrus. Since there are potential side effects such as prolonged estrus, pyometra, and aplastic anemia (pancytopenia), it should be documented that the bitch was actually bred based on owner observation of a mating or laboratory identification or the presence of sperm cells in a vaginal swab. Sperm cells can be identified in 100% of bitches mated within 24 hours and 75% of bitches mated within 48 hours by placing the tip of the vaginal cytology swab into a tube containing 0.5 ml saline for 10 minutes, squeezing the swab dry into a tube and centrifuging the fluid at $2000 \times g$ for 10 minutes, and finally staining the sediment (Whitacre et al., 1992).

Estradiol cypionate (ECP, Pharmacia) was shown to have 100% efficacy and no side effects during the study period when administered at a dose of 44 mcg/kg intramuscularly one time during estrus; however, a 25% (1/4) incidence of pyometra was seen when administered during diestrus (Bowen et al., 1985). Estradiol benzoate (Oestradiol Benzoate, Intervet) at a dose of 0.01 mg/kg

intramuscularly at 3 and 5 days (and occasionally 7 days) after mating in 358 bitches resulted in only 4.5% (16/358) of the bitches actually whelping; in none of the bitches was bone marrow aplasia reported. The 7.3% incidence of pyometra reported was not different from the normal prevalence reported as 2% to 10% (Sutton, Geary, and Bergman, 1997). Administration of diethyl stilbestrol is not effective as a mismatch therapy (Bowen et al., 1985).

I do not encourage estrogen use routinely because alternative treatments after the bitch is diagnosed pregnant are probably better; however, their use is not unconditionally condemned as malpractice.

DRUGS USED DURING CONFIRMED PREGNANCY

If the bitch is mated or thought to have been mated, it is best to wait and perform a pregnancy diagnosis before proceeding to terminate pregnancy. Even though conception rates in controlled breeding situations resulted in a pregnancy rate of about 90% when only a single mating was allowed on any day of estrus (up to the last 2 days of estrus) (Holst and Phemister, 1974), only 38% of bitches presented for mismatch may actually be pregnant (Feldman et al., 1993). A pregnancy examination should be performed at least 30 to 40 days after the last possible breeding to minimize false-negative diagnoses caused by errors in calculating the gestation duration from a mating that occurred early in estrus. Only if a bitch is pregnant should therapy be instituted. Drugs that terminate pregnancy can cause luteal demise by direct luteolytic action, inhibiting prolactin synthesis, acting as a progesterone inhibitor, or unknown mechanisms.

Prostaglandins work by lysing the corpora lutea. The natural $\text{PGF}_{2\alpha}$ (Lutalyse, Pharmacia) given at a dose of 0.1 to 0.25 mg/kg BID or TID subcutaneously is very effective at terminating pregnancy. A protocol found to have the fewest side effects is $\text{PGF}_{2\alpha}$ administered at a dose of 0.1 mg/kg every 8 hours subcutaneously for 2 days and then 0.2 mg/kg every 8 hours subcutaneously until abortion is complete (Feldman et al., 1993). Abortion is usually complete within 9 days, but some bitches abort fetuses and still have live fetuses after 9 days. It is extremely important to continue the treatments until abortion is complete. Side effects include vomiting, diarrhea, and possibly circulatory collapse. The side effects usually subside within 20 minutes, but the bitch should be monitored carefully during this time. To minimize caloric loss, bitches should be fed at least 1 hour after treatment. To shorten the treatment period required to induce abortion with natural prostaglandin, a combination of prostaglandin at a

dose of 0.1 mg/kg TID subcutaneously for 2 days and then at a dose of 0.2 mg/kg TID subcutaneously to effect was administered with misoprostol (Cytotec, Pharmacia) at a dose of 1 to 3 mcg/kg SID deposited into the cranial vaginal vault. The mean time to complete abortion using this combination was 5 days compared to a mean of 7 days for prostaglandin alone (Davidson, Nelson, and Feldman, 1997).

Synthetic prostaglandins are more potent and have fewer side effects than natural prostaglandins. Cloprostenol and fluprostenol (Equimate, Bayer) are both effective for inducing abortion (Jackson, Furr, and Hutchinson, 1982; Shille, Dorsey, and Thatcher, 1984). Cloprostenol (Estrumate, Schering-Plough) at a dose of 1 to 2.5 mcg/kg SID subcutaneously for 4 to 5 days was 100% effective at inducing abortion after a 4- to 7-day treatment regimen, and the side effects were noted to be minimal to none at a 1-mcg/kg SID subcutaneous dose (Verstegen, 2000). Once-daily treatments provide an advantage over the every-8-hour treatments required when using the natural prostaglandin. Hospitalization and/or frequent injections add greatly to the client cost when using prostaglandins as abortifacients.

The dopaminergic drugs are prolactin inhibitors. Prolactin inhibitors currently available include bromocriptine and cabergoline. Bromocriptine (Parlodel, Sandoz) administered at a dose of 62.5 mcg/kg BID orally to dogs at 43 to 45 days after ovulation resulted in only two of four bitches aborting; side effects included emesis and loose stools (Wichtel et al., 1990). Because the dose is so low and the tablets contain so much active drug, the bromocriptine tablets can be crushed and dissolved in water to ease dosing. Cabergoline (Dostinex, Pharmacia) at a dose of 1.65 mcg/kg SID subcutaneously for 5 to 6 days at 25 to 40 days after the first mating resulted in abortion for all (5/5) bitches greater than 40 days' gestation but only for 50% (1/4 at 25 days and 4/6 at 30 days) of those less than 40 days (Onclin et al., 1993). Side effects were minimal, and bitches that aborted were bred successfully after treatment. Only an oral 0.5-mg tablet of cabergoline is available in the United States; when given at a dose of 160 mcg orally to a 32-kg German shepherd dog after 40 days of gestation, it resulted in abortion after 7 days with no side effects (Arbeiter and Flatscher, 1996). Although cabergoline is not very expensive for each dose, it may be difficult to administer because the tablets are 0.5 mg and the dose for a 10-kg dog is only 0.05 mg. An oral solution can be made to dissolve and dilute the tablets. Even though each dose of cabergoline may be only about \$1.80, an initial investment of around \$145 is necessary to purchase the minimum package.

In an effort to reduce the side effects and increase the efficacy of prostaglandins and prolactin inhibitors, a combination of the two has been used. Cloprostenol at a dose of 1 or 2.5 mcg/kg SID subcutaneously in combination with cabergoline at a dose of 1.65 mcg/kg SID subcutaneously for 5 days from midgestation induced abortion with no adverse side effects at the low dose (Onclin, Silva, and Verstegen, 1995). Cabergoline at a dose of 5 mcg/kg SID orally 1 hour after cloprostenol at a dose of 1 mcg/kg every 48 hours subcutaneously caused fetal death with no side effects after a mean of three injections (9 days) when

started 25 days after the luteinizing hormone peak (Onclin and Verstegen, 1996). Treatments of cabergoline at a dose of 5 mcg/kg SID orally for 10 days combined with either a single cloprostenol injection of 2.5 mcg/kg subcutaneously at the start of the treatment or two doses of 1 mcg/kg subcutaneously at the start of the treatment and 4 days later were successful at inducing resorption. Similarly bromocriptine administered at a dose of 30 mcg/kg TID orally for 10 days plus either a single dose of 2.5 mcg/kg subcutaneously of cloprostenol or two doses subcutaneously of 1 mcg/kg cloprostenol was also successful at inducing resorption (Onclin and Verstegen, 1999). All bitches in the aforementioned study became pregnant during the subsequent estrus cycle, which occurred sooner than normally anticipated.

The antiprogesterone compound mifepristone, more commonly known as RU486 or RU 38486 for its use in preventing human pregnancies, administered at a dose of 2.5 mg/kg BID orally for 4.5 days starting at day 32 of gestation resulted in 100% (5/5) of the bitches having pregnancy loss around 3 days after treatment initiation, with no side effects (Concannon, Yeager, and Concannon, 1990). Doses as low as 8.3 mg/kg and up to 20 mg/kg SID orally for one or two treatments resulted in abortion within 2 to 11 days at days 35 to 39 of pregnancy (Linde-Forsberg, Kindahl, and Madej, 1992). Mifepristone (Mifeprex, Danco) is only available as a human-labeled 200-mg tablet in the United States and can cost as much \$90 a dose for a 10-kg dog; an initial purchase of \$270 is required to purchase a package of the drug. Aglipristone (Alizine, Virbac) is another progesterone blocker that is available in France, Norway, and Sweden but not in the United States to terminate pregnancy in the bitch. Two doses of 0.33 ml/kg SID subcutaneously for 2 days caused uncomplicated abortions within 14 days in 94.4% (117/124) of bitches after 26 days of pregnancy (Fieni et al., 2001). A brown mucoid vaginal discharge was seen 24 hours before fetal expulsion, and other side effects included slight depression, transitory anorexia, and mammary gland congestion.

Although the mechanism of action is not completely known, dexamethasone was effective at inducing fetal resorption from midgestation with the use of a 9.5-day dosage schedule as follows: 0.2 mg/kg orally BID for 7 days, 0.16 mg/kg orally on the morning of the eighth day, 0.12 mg/kg orally in the evening of the eighth day, 0.08 mg/kg orally in the morning of the ninth day, 0.04 mg/kg orally in the evening of the ninth day, and 0.02 mg/kg orally the morning of the tenth day. Pregnancies less than 40 days generally had no fetuses expelled, and the majority had no external signs of pregnancy loss except for a mild vaginal discharge seen in about 34% (26/75) of the bitches that resorbed fetuses (Zone et al., 1995; Wanke et al., 1997). Abortion or resorption generally was complete 10 to 23 days after the treatment started (Wanke et al., 1997). The main side effects of dexamethasone treatment included anorexia; polydipsia; and polyuria, which usually began around 2 to 3 days after treatment started, was greatest 4 to 5 days later, and then subsided 3 to 4 days after the termination of treatment. Successful pregnancies were obtained in 18 of 20 bitches bred during the first

estrus after treatment and 2 of 2 on the second estrus. At my institution an oral dose of 0.2 mg/kg BID until fetal resorption occurs is used, with no tapering of the dose. I have observed no more than the anticipated normal side effects from not tapering the dose. Dexamethasone eliminates most of the side effects seen with other drugs and avoids the requirement for hospitalization or office visits for injections. Since dexamethasone is inexpensive, readily available, can be administered easily by clients, is effective, and has few side effects, it is my choice for terminating pregnancy in the bitch.

Several other drugs have been used to terminate pregnancy in the bitch, including tamoxifen citrate (Taxol, Bristol-Meyers Squibb), which acts as an estrogen; epostane, which inhibits steroid synthesis by inhibition of 3 β hydroxysteroid dehydrogenase; and Δ 5-4 isomerase and isoquinolones L-12717 (Lotifren). These are either not efficacious or not available in the United States.

Inherited Disorders of the Reproductive Tract in Dogs and Cats

VICKI N. MEYERS-WALLEN, *Ithaca, New York*

NORMAL SEXUAL DEVELOPMENT

Normal sexual development depends on successful completion of three consecutive steps: (1) establishment of chromosomal sex, (2) development of gonadal sex, and (3) development of phenotypic sex. *Chromosomal sex*, which corresponds to genetic sex in normal animals, is established at fertilization. The zygote receives either two X chromosomes or an X and a Y chromosome and maintains this chromosomal constitution in all cells by mitotic division. Morphology of early XX and XY embryos is sexually indifferent. Both have a genital ridge, from which the testis or ovary will develop. They also have müllerian and wolffian ducts, a urogenital sinus, a genital tubercle, and genital swellings, from which the internal and external genitalia will arise (Fig. 224-1). Differentiation of the genital ridge into a testis or an ovary defines gonadal sex and marks the end of the sexually indifferent stage. Although several genes undoubtedly are necessary for normal development through the sexually indifferent stage, genes that determine gonadal sex have a pivotal role in sexual development.

Gonadal sex is normally determined by sex chromosome constitution: presence of the Y chromosome results in testis development, whereas its absence results in ovarian development. The sex-determining region Y gene, *Sry*, is normally located on the Y chromosome. This gene encodes the testis-determining factor and is the genetic signal for initiating testis differentiation in the genital ridge (reviewed in Goodfellow and Lovell-Badge, 1993). *Sry* is distinctly different from the gene for H-Y antigen, which is no longer thought to have a role in testis induction. Transgenic experiments in mice have demonstrated that *Sry* is the only Y-linked gene needed for testis induction (Koopman et al, 1991), and other evidence supports this theory (reviewed in Goodfellow and Lovell-Badge, 1993). In the absence of the Y chromosome and *Sry*, the genital ridge normally becomes an ovary. Although several genes have been identified as having roles in ovarian differentiation, none has yet been shown to have a role analogous to that of *Sry* in testis induction. However, ovarian induction is not a passive process, as it is now recognized that both testis-promoting and ovary-promoting signaling pathways are responsible for gonadal sex determination (DiNapoli and Capel, 2008).

Phenotypic sex is normally controlled by gonadal sex. If the genital ridges are removed from XX or XY embryos before gonadal differentiation occurs, a female phenotype develops. This indicates that the embryo is programmed

to develop as a female and must be diverted from this pathway to develop as a male. The critical diverting step is testis development. The testis secretes two substances that act within an embryonic critical period to induce masculinization: (1) müllerian inhibiting substance (MIS), which causes the müllerian ducts to regress, and (2) testosterone, which stimulates formation of the vasa deferentia and epididymides from the wolffian ducts (see Fig. 224-1). In the external genitalia, testosterone (T) is converted to dihydrotestosterone (DHT) by the enzyme 5 α -reductase. Dihydrotestosterone stimulates formation of the prostate and male urethra, penis, and scrotum from the urogenital sinus, genital tubercle, and genital swellings, respectively (see Fig. 224-1). Descent of the testes into the scrotum completes the male external genitalia, but the genetic and hormonal control of this process is incompletely understood. Testosterone and insulin-like 3 factor (*InsI3*), both secreted by Leydig cells, are required for testis descent, but other, unknown factors are also likely to be involved (Tomboc et al, 2002). In the absence of a testis and its masculinizing hormones, female genitalia develop (see Fig. 224-1).

DIAGNOSIS OF DISORDERS OF SEXUAL DEVELOPMENT

Intersex is a general term used to describe an animal with ambiguous genitalia. However, it is nonspecific, in that ambiguous genitalia can arise from an abnormality at any step in sexual development. Disorders in sexual differentiation can be classified by the initial step at which development differs from normal, thus falling into three general categories: abnormalities of chromosomal sex, gonadal sex, and phenotypic sex (Table 224-1). A more precise diagnosis, which defines the disorder according to its etiology, should be made when such information can be obtained. In the near future, for example, these disorders are likely to be defined by the specific gene mutation that is responsible for the defect.

The diagnostic plan should include investigation of chromosomal sex by direct examination of the chromosomes and construction of a karyotype. The presence or absence of the *Sry* gene in dogs can also be examined by molecular assays, such as polymerase chain reaction (see XX sex reversal later). Gonadal sex is best determined by histology and may require serial gonadal sections for identification of the ovotestes. A concise description of the internal and external

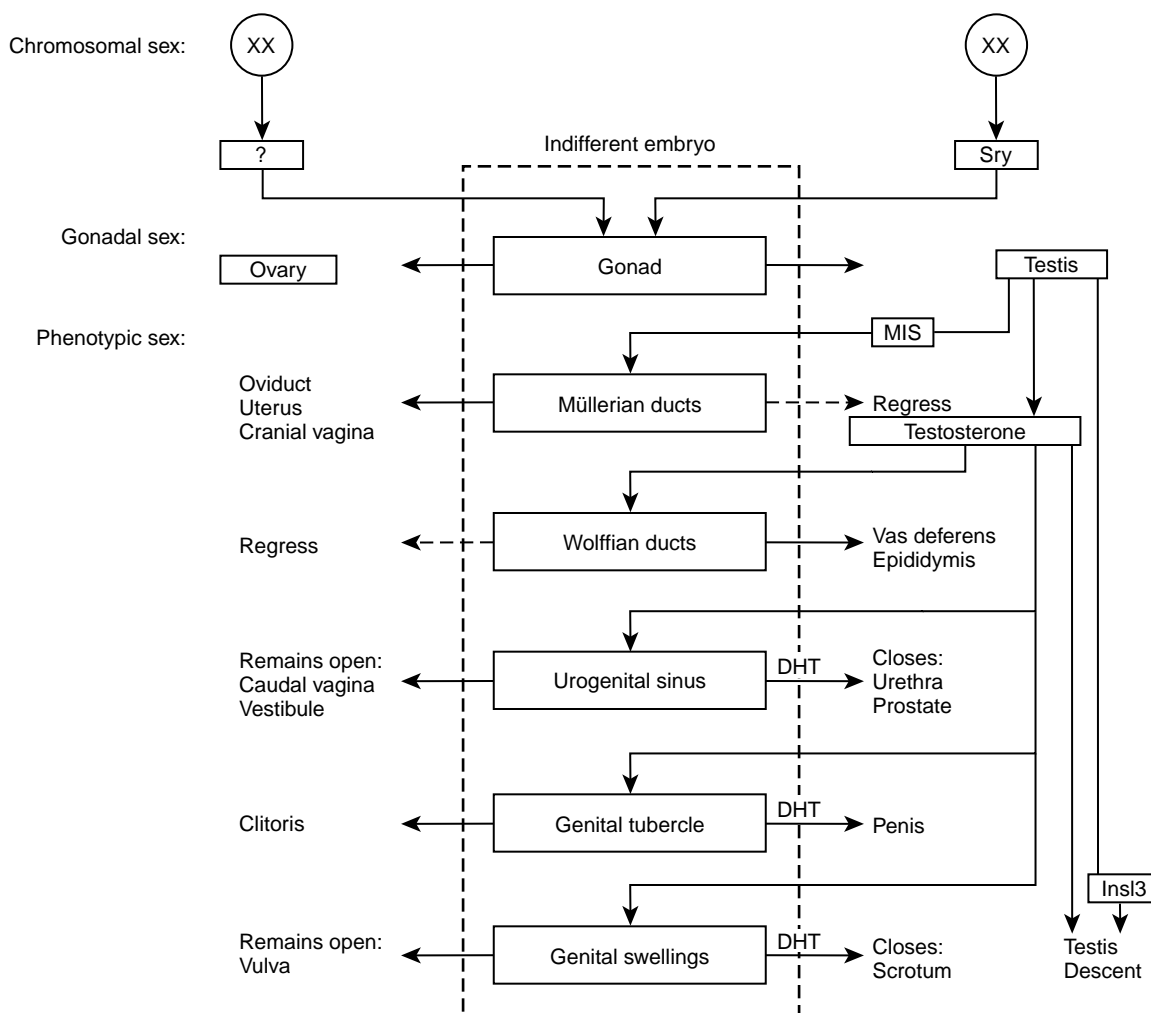

Fig 224-1 Normal sexual development. (Modified from Morrow DA: Current therapy in theriogenology, ed 2, Philadelphia, 1986, Saunders, with permission.)

genitalia is necessary for defining phenotypic sex. Assays of peripheral hormones may be helpful, but gonadotropin-releasing hormone (GnRH) or human chorionic gonadotropin (hCG) stimulation tests are necessary in many cases, particularly those in which peripheral androgen concentrations are of concern (Shille and Olson, 1989).

Abnormalities of Chromosomal Sex

Many disorders of sexual differentiation have been reported in which the primary cause was an abnormality in the number or structure of the sex chromosomes (reviewed in Meyers-Wallen and Patterson 1989a). To summarize, animals with abnormalities in sex chromosome number, such as those with XXY and XO syndromes, generally have underdeveloped genitalia and are sterile but are unambiguously male or female in phenotype (see Table 224-1). The gonadal sex of chimeras and mosaics depends on the distribution of XX and XY cells within the genital ridge. Phenotypic sex is then determined by the presence and amount of functional testicular tissue in the gonad. Abnormalities in chromosomal sex are usually due to chance events, such as errors in chromosome segregation or fusion of zygotes. Therefore, familial aggregation of affected individuals is not expected.

Abnormalities of Gonadal Sex

In this category, there is disagreement between the chromosomal sex and the gonadal sex of the individual. These animals are termed *sex-reversed*. In XX sex reversal, the chromosome constitution is XX but the individual develops testicular tissue in the gonad (testis or ovotestis). This has been reported in dogs, but not in cats.

XX Sex Reversal

Dogs affected with XX sex reversal have a 78,XX chromosome constitution and varying amounts of testicular tissue in the gonad. Affected dogs are termed either *XX true hermaphrodites*, which have at least one ovotestis, or *XX males*, which have bilateral testes (see Table 224-1). Both phenotypes can appear in the same family. Phenotypic masculinization is dependent on the amount of testicular tissue in the affected individual. Thus, XX true hermaphrodites may have normal female external genitalia or have an enlarged clitoris with an os clitoris that resembles a penis or have any phenotype in between. XX males generally have a caudally displaced prepuce and a penis with hypospadias and are bilaterally cryptorchid. XX sex reversal has been reported as a familial disorder in the English cocker spaniel, beagle,

Table 224-1

Main Features of Selected Disorders of Sexual Development*

Abnormality of	Karyotype	Gonad	Müllerian Duct Derivates	Wolffian Duct Derivates	External Genitalia	Diagnosis
Chromosomal sex	XXY	Testis	None	Epididymis, vas deferens	Male	XXY syndrome
	X0	Streak gonad	Uterus, oviduct vagina	None	Female	X0 syndrome
	XX/XY	Ovary or ovotestis or testis	Varies depending on amount of functional testis		Female or ambiguous or male	Chimera
Gonadal sex	XX	Testis	Uterus	Epididymis, +/- vas deferens	Cryptorchid, hypospadias, displaced prepuce	XX sex reversal (<i>Sry</i> -negative): XX male
	XX	Ovotestis	Uterus ± oviduct	+/- epididymis	Female or enlarged clitoris	XX true hermaphrodite
Phenotypic sex						
Female pseudohermaphrodite	XX	Ovary	Uterus, oviduct	+/- epididymis	Ambiguous or male	Exogenous androgen or progestagen
Male pseudohermaphrodite	XY	Testis	Uterus, oviduct	Epididymis, vas deferens	Male +/- cryptorchid	Persistent Müllerian duct syndrome
	XY	Testis	None	None	Female	Complete Tfm
	XY	Testis	None	+/- epididymis +/- vas deferens	Ambiguous or Female	Incomplete Tfm

*Examples are disorders reported in dogs or cats.

weimaraner, Kerry blue terrier, Chinese pug (reviewed in Meyers-Wallen and Patterson, 1989a), and German short-haired pointer (Meyers-Wallen et al., 1995b). It is likely to be inherited in all of these breeds, but the mode of inheritance has not been determined. In the American cocker spaniel, XX sex reversal is inherited as an autosomal recessive trait (Meyers-Wallen and Patterson, 1988). *Sry*-negative XX sex reversal has also been reported in a number of other dog breeds (Meyers-Wallen et al., 1999; Melniczek et al., 1999; De Lorenzi et al., 2008).

Diagnosis of XX sex reversal classically depends on confirmation of a 78,XX chromosome constitution and the presence of at least one ovotestis or testis. Whereas elevation in peripheral T concentrations in response to GnRH or hCG stimulation strongly suggests that testicular tissue is present, it is not diagnostic (Shille and Olson, 1989). The inability to provoke T elevation by a stimulation test does rule out the diagnosis of XX sex reversal. Histologic demonstration of testicular tissue in at least one gonad in a 78,XX dog is necessary for a definitive diagnosis. To define the etiology of XX sex reversal more precisely and aid in genetic counseling, the diagnostic work-up should include a molecular test for the presence or absence of *Sry*. For example, in most humans with XX sex reversal, a Y chromosome is not detectable in the karyotype, yet the *Sry* gene is present, as demonstrated by molecular techniques such as PCR. These *Sry*-positive XX individuals have received an *Sry* translocation from the parent. That is, the *Sry* gene has been transferred from the Y to another chromosome through abnormal crossing over, probably during gamete formation. Therefore only one affected individual with *Sry*-positive XX sex reversal usually occurs within a family. *Sry*-positive XX sex reversal has not been reported in the dog. In addition to dogs

(Meyers-Wallen et al., 1995a, 1995b), *Sry*-negative XX sex reversal has been reported in humans (reviewed in Sarafoglou and Ostrer, 2000), goats (Pailhoux et al., 2001), pigs (Pailhoux et al., 1994), horses (Buoen et al., 2000; Meyers-Wallen et al., 1997) and llamas (Drew et al., 1999; Wilker et al., 1994). There is no *Sry* translocation detectable in these affected individuals, because the *Sry* gene is truly absent. Causative mutations have been identified only in humans and goats. In one human XX male, a *Sox9* duplication was identified (Huang et al., 1999), which was proposed to cause *Sox9* overexpression, as in transgenic mouse models of this disorder (Bishop et al., 2000). Recently mutations in *R-spondin1* (*Rspo1*) were identified as the cause of XX males in one human family (Parma et al., 2006). Subsequently, a different *Rspo1* mutation was identified in an XX true hermaphrodite in another family (Tomaselli et al., 2008). In polled goats, the causative defect is a deletion that removes the regulatory region for at least three genes. However, mutations in the homologous region have not been associated with sex reversal in other mammals, including dogs (Kothapalli et al., 2003; Pujar et al., 2007).

This form of canine sex reversal has been studied most extensively in a pedigree derived from the American cocker spaniel, in which an autosomal recessive mode of inheritance was identified through experimental matings (Meyers-Wallen and Patterson, 1988). A genome-wide linkage analysis in this model pedigree identified linkage to CFA29 (Pujar et al., 2007). Neither *Sox9* nor *Rspo1* is located in this region, and a candidate gene has not been identified. The causative mutation is likely to be the same in American and English cocker spaniels, because they share recent common ancestry. It is unclear whether the same gene locus is responsible in other breeds (De Lorenzi et al., 2008).

XX males are sterile, as are most XX true hermaphrodites. Treatment of XX true hermaphrodite and XX male dogs is limited to surgical removal of the gonads and uterus and, if the dog is uncomfortable, excision of the enlarged clitoris and os clitoris. During breeding studies in the American cocker spaniel, some XX true hermaphrodites had estrous cycles and a few produced offspring. Nevertheless, the mating of affected dogs of any breed is strongly discouraged, as it will increase the frequency of the causative mutation within the breed. Similarly, parents of affected dogs should not be bred. As the causative mutation is unknown, a laboratory test for detecting carriers or affected dogs is not available. Currently there is no practical method of determining which siblings of affected dogs carry the causative mutation.

Abnormalities of Phenotypic Sex

The chromosomal and gonadal sex are in agreement in these animals, yet the internal or external genitalia are ambiguous. Affected individuals are generally termed either *male* or *female pseudohermaphrodites* (see Table 224-1).

Female Pseudohermaphroditism

Female pseudohermaphrodites have an XX chromosome constitution and bilateral ovaries. Development of ambiguous genitalia is due to the presence of exogenous or endogenous androgens during development (Meyers-Wallen and Patterson, 1989a). The canine cases were XX individuals with bilateral ovaries and phenotypic masculinization ranging from mild clitoral enlargement to nearly normal male external genitalia with an internal prostate. An iatrogenic cause was known in some cases: either an androgen or a progestagen had been administered during gestation. The presenting signs were related to bleeding at the onset of proestrus, urinary incontinence, or uterine infection.

Although adrenal enzyme defects (adrenogenital syndromes) are a common cause of female pseudohermaphroditism in humans, they are apparently rare in dogs and cats. However, excess adrenal androgen production due to 11 beta-hydroxylase deficiency has been reported in a calico cat that presented with male external genitalia, but no testes palpable in the scrotum (Knighton, 2004). Internal genitalia consisted of ovaries, bicornuate uterus, and oviducts, and the karyotype was that of a normal female (38,XX). Clinical signs included polydipsia, polyuria, and inappropriate urination. After ovariectomy, penile spines persisted and peripheral testosterone concentrations were in the normal range of an intact male.

Diagnosis of female pseudohermaphrodites depends on confirmation of an XX chromosome constitution and ovaries. Before the gonads are removed, the diagnostic work-up could include tests for investigating endogenous androgen production (Shille and Olson, 1989). Elevation of serum T in response to GnRH or hCG would suggest testicular androgen production. Along with an XX chromosome constitution, this result would suggest a diagnosis of XX sex reversal (see earlier), and not female pseudohermaphroditism. Gonadal histology is necessary for distinguishing the difference. Abnormal elevation of serum androgens in response to adrenocorticotrophic hormone stimulation would suggest adrenal androgen production, such as in the

human adrenogenital syndromes. If no evidence of endogenous androgen production is found, historical confirmation of exogenous androgen exposure should be sought.

Ovariectomy, with gonadal histopathology, is recommended for female pseudohermaphrodites. However, when urinary abnormalities are present, contrast studies are recommended before surgery to determine whether additional surgical treatment is necessary. As the most common cause is iatrogenic androgen administration, prevention may be best achieved by avoidance of steroid administration, such as androgens or progestagens, during gestation. Because the canine internal and external genitalia normally develop between gestational days 34 and 46, counting from the serum luteinizing hormone peak of the dam (Meyers-Wallen et al, 1991, 1993), it would be prudent to avoid steroid administration during this period.

Male Pseudohermaphroditism

A male pseudohermaphrodite has an XY chromosome constitution and testes, yet has female internal or external genitalia to some degree (see Table 224-1). Obviously this definition excludes XX males, in which chromosomal and gonadal sex do not agree (see XX sex reversal earlier). Two etiologically distinct categories of male pseudohermaphroditism are recognized: (1) failure of müllerian duct regression (as in persistent müllerian duct syndrome) and (2) failure of androgen-dependent masculinization (including defects in androgen synthesis, 5 α reductase, or the androgen receptor).

Persistent Müllerian duct syndrome. Persistent müllerian duct syndrome (PMDS) has been reported in the miniature schnauzer in the United States and the basenji in the Netherlands and may also occur in the Persian cat (reviewed in Meyers-Wallen and Patterson, 1989a). Affected miniature schnauzers are XY males with bilateral testes and normal androgen-dependent masculinization of the internal and external genitalia. However, they also have bilateral oviducts, a complete uterus with cervix, and the cranial portion of the vagina. Approximately half of affected dogs have unilateral or bilateral cryptorchidism, while the remaining half have normally descended testes. Therefore affected males may not be detected by physical examination alone. Affected males are frequently detected when clinical signs related to pyometra, urinary tract infection, prostate infection, or neoplasia in cryptorchid testes arise.

Diagnosis of PMDS depends on confirmation of an XY chromosome constitution, bilateral testes, and the presence of all müllerian duct derivatives (see Table 224-1). Treatment is limited to castration and hysterectomy. The uterine body terminates in a small cervix and cranial vagina at the craniodorsal aspect of the prostate gland. In some cases, there is a short, small-diameter communication between the cranial vaginal portion and the prostatic urethra, which may allow ascending infection to the uterus. During hysterectomy, care should be taken to remove as much of the vaginal portion as possible.

Prevention is limited to removing affected and carrier dogs from the breeding population. In the miniature schnauzer, PMDS is inherited as an autosomal recessive trait (Meyers-Wallen et al, 1989c). Although both females and males can be carriers, only homozygous males express

the affected phenotype. Affected dogs with scrotal testes are usually fertile, but breeding of such dogs is strongly discouraged. Affected dogs will transmit the PMDS trait to all of their offspring, producing only carriers or affected dogs. The etiology of this defect is unknown. Affected dogs produce biologically active MIS during the embryonic critical period for müllerian duct regression (Meyers-Wallen et al, 1989c, 1993). Therefore, it is suspected that the müllerian ducts are insensitive to MIS, possibly because of a receptor defect.

Defects in Androgen-Dependent Masculinization. Affected animals in this category are XY males that have bilateral testes and normal regression of the müllerian duct system. However, genitalia that require androgens for masculinization fail to develop normally (see Table 224-1). Inherited defects of this type generally affect both prenatal and postnatal male development. Failure of androgen-dependent masculinization can range from mild (incomplete failure) to severe (complete failure). The primary defect causing these phenotypes may lie in (1) androgen production, (2) conversion of T to DHT, or (3) androgen reception at the target organ level. Defects in androgen production have not been documented in the dog or cat. The terms *androgen resistance* and *androgen insensitivity* refer to syndromes in which androgen production is normal but there is still failure of masculinization. These include defects in the 5 α -reductase enzyme and the androgen receptor. Defects in 5 α -reductase affect conversion of T to DHT and have not been reported in dogs and cats. The term *testicular feminization* is reserved for androgen receptor defects. In the testicular feminization syndromes, both T- and DHT-dependent masculinization can be affected, resulting in either complete or partial failure of masculinization (see Table 224-1). Defects of this type have been reported in dogs and cats.

Hypospadias. Hypospadias is an abnormality in location of the urinary orifice caused by incomplete masculinization of the urogenital sinus during formation of the male urethra. As a result, the urethral opening may be located anywhere along the embryologic course of the urogenital sinus to the genital tubercle. Hypospadias has been reported as a familial defect in some dog breeds, particularly in the Boston terrier, whereas teratogen-induced hypospadias has been reported in other species (see *CVT X*, p. 1267, reviewed in Meyers-Wallen and Patterson, 1989a). The initial differential diagnosis may include inherited defects such as XX sex reversal, particularly when hypospadias is accompanied by scrotal abnormalities or a uterus. A diagnostic plan that includes investigation of chromosomal and gonadal sex will lead to appropriate diagnosis and genetic counseling. Surgical correction of this defect is usually unnecessary, because hypospadias does not usually cause urinary difficulties. Affected dogs with mild hypospadias may be able to breed normally. However, when the etiology of hypospadias is unknown, it is recommended that affected dogs be removed from the breeding program to prevent further dissemination of familial hypospadias.

Testicular feminization syndromes. Testicular feminization syndromes are caused by mutations in the X-linked androgen receptor gene. Affected individuals are XY males with bilateral testes (see Table 224-1). Müllerian duct derivatives are absent, as expected for a male. However, there is either

complete or partial failure of androgen-dependent masculinization, depending on whether the androgen receptor is nonfunctional or partially functional. Although T production and conversion to DHT are normal, the target organs are unable to respond appropriately.

In complete testicular feminization, the androgen receptor is completely nonfunctional and androgen-dependent masculinization is entirely absent. Affected males often present as females that fail to cycle and are sterile. A defect of this type has been reported in a domestic shorthaired cat (Meyers-Wallen et al., 1989b). Bilateral abdominal testes were present, but there were no epididymides nor vasa deferentia. The uterus was absent as expected, because MIS production and response is unaffected. The external genitalia were phenotypically female. High-affinity binding of DHT was virtually undetectable in cultured genital fibroblasts, confirming receptor malfunction.

In humans, incomplete testicular feminization syndromes are caused by different mutations of the androgen receptor gene that produce varying degrees of masculinization. The spectrum caused by these defects ranges from individuals with ambiguous genitalia to phenotypic males that are infertile. The author has observed a number of cats that probably have incomplete testicular feminization syndromes. They were XY and had bilateral testes within a bifid scrotum. The external genitalia resemble that of a female, in that there is a vulva-like genital opening with a female urethral orifice and a blind-ending vagina. There are severe perineal hypospadias, and the penis resembles a clitoris, yet develops spines. Studies in one cat indicated that neither T nor DHT was deficient (Meyers-Wallen and Patterson, 1989a). Although androgen-receptor assays were not performed, this suggests that the partial masculinization was due to an androgen-receptor defect in which the receptor was partially functional.

A similar case has been described in a mixed breed dog (Peter et al., 1993). In this XY male with bilateral testes in a bifid scrotum, the testes appeared as swellings on each side of a vulva that opened into a blind vaginal pouch. Peripheral T and DHT concentrations were normal after hCG stimulation. Epididymides were present adjacent to the testes, indicating that T-dependent masculinization was unimpaired during embryonic development. High-affinity binding of DHT was undetectable in cultured genital fibroblasts. These data suggest that DHT binding was abnormal but T binding was not. Both T and DHT bind to the same androgen receptor, which is encoded by a single gene. Nevertheless, there is pharmacologic evidence that the androgen receptor can exhibit different binding affinity preference for DHT relative to T in adult canine tissues (Summerfield et al., 1995). Therefore it is possible that a mutation in the androgen receptor could affect DHT-dependent masculinization but not T-dependent masculinization, as the findings in this case would suggest.

Diagnosis of a testicular feminization syndrome is dependent on demonstration of an XY chromosome constitution, bilateral testes, and abnormal androgen binding in androgen-responsive tissues. GnRH/hCG stimulation tests in the intact animal will confirm that peripheral androgens are present (Shille and Olson, 1989), providing further evidence for androgen resistance. In the future, when the range of canine and feline androgen receptor mutations has been documented as in humans, it should

be possible to diagnose these defects at the level of the androgen receptor gene. Castration is the recommended treatment for affected dogs and cats. Prevention is limited to genetic counseling regarding the X-linked inheritance of this disorder. Carrier females are fertile. Of their offspring, 50% of the males are expected to be affected, whereas 50% of the females are expected to be carriers. However 50% of the male offspring will not receive the X chromosome bearing the testicular feminization mutation. These males should have normal genitalia and can be used in a breeding program.

Cryptorchidism. Cryptorchidism is included here somewhat arbitrarily because the underlying mechanisms for abnormal testis descent are incompletely understood. Cryptorchidism is associated with other defects in sexual development, as mentioned earlier, but can also appear as the only defect of the reproductive system, which is referred to here as isolated cryptorchidism. As previously reviewed (Meyers-Wallen and Patterson, 1989a), isolated cryptorchidism is the most common disorder of the reproductive tract reported in dogs. A diagnosis of cryptorchidism is warranted if both testes are not palpable within the scrotum at 8 weeks of age because the testes normally descend by 10 days after birth. Although canine testis descent later than 10 days is anecdotally known to most veterinarians, the frequency of such delayed descent is unknown. In one study (Dunn et al., 1968), pups with cryptorchidism were examined every 2 weeks from 6 to 14 weeks of age, then again at 6 and 12 months of age. They observed that 24.6% of cryptorchid testes descended by 6 months of age, with the majority descending by 14 weeks of age. Testis descent after 6 months of age was not observed in any case monitored. There is evidence in humans and mice that delayed testis descent is a variation of cryptorchidism rather than a variation of normal. For example, delayed testis descent was observed in humans with heterozygous *Ins13* mutations (Tomboc et al., 2002).

Dogs with bilateral cryptorchidism are sterile, whereas those with unilateral cryptorchidism can be fertile. However, the recommended treatment for both is bilateral castration. First, there is an increased risk of Sertoli cell tumor in cryptorchid testes. Second, isolated cryptorchidism is clearly a familial trait in several breeds and is likely to be inherited in dogs, as it is in other mammals. Although mutations in *Ins13* and its receptor have been identified to cause cryptorchidism in mice and humans, mutations in these genes have not been identified in cryptorchid dogs. Furthermore, mutations in those genes account for a small number of human cases (1.4%, Tomboc et al., 2002), indicating that additional genes are likely to play a role in cryptorchidism.

Although the genetics of this disorder in dogs are incompletely characterized, there are enough data to allow genetic counseling. Inheritance of isolated cryptorchidism as a sex-limited recessive trait is consistent with available data. Using this model, the first recommendation is that affected dogs be removed from the breeding population. The second recommendation is that both the father and mother of affected dogs should be considered to be carriers. Some full siblings of the affected dog will also be carriers. In other species in which cryptorchidism occurs as a simple (single-gene) recessive trait, a reduction in the frequency of affected animals was obtained in a few generations by removing carrier parents and affected

males from the breeding population. This is probably the minimum program that should be pursued in dogs. It may also be necessary to remove siblings of affected dogs from the breeding program. Although medical regimens have been suggested to induce testicular descent in cryptorchid dogs, there are no published reports to confirm that these are more successful than no treatment, in which 24.6% of cryptorchid testes could descend by 6 months of age. Furthermore, even if delayed testis descent occurs, the genes responsible for cryptorchidism remain unchanged and will be transmitted to the offspring.

It is recommended that cryptorchid dogs and those with late testicular descent be removed from the breeding program to reduce the gene frequency of these disorders in the breed.

CHAPTER 225

Ovarian Remnant Syndrome in Cats

MARGARET V. ROOT KUSTRITZ, *St. Paul, Minnesota*

Ovarian remnant syndrome (ORS) is a complication of ovariectomy, defined as appearance of estrous behavior in an ovariectomized female cat. Onset of estrous behavior may occur weeks to years after ovariectomy and assumes normal cyclicity once it begins. The only other differential for estrous behavior in an ovariectomized animal is secretion of sex hormones from the adrenal gland; this is extremely uncommon and would not be likely to be cyclic.

One possible cause of ORS is surgeon error. It has been demonstrated that pieces of ovarian tissue left free floating in the abdomen or sutured to the mesentery can revascularize and become functional (DeNardo et al., 2001; Shemwell and Weed, 1970). However, the relative ease of ovariectomy in the cat is at odds with the apparent incidence of the disorder; true incidence is unknown. Another possible cause of ORS is presence of an accessory piece of ovary, located well away from the main ovary in the ovarian ligament, which becomes functional after removal of the main ovary. At present there is no technique allowing definitive differentiation of the possible causes.

Diagnosis requires demonstration of estrogen secretion followed by progesterone secretion after induction of luteinization. The following diagnostic plan is defini-

tive for ORS since only ovarian tissue can secrete estrogen and then be induced to secrete progesterone.

1. See the queen when the owner perceives her to be in estrus.
2. Collect a vaginal cytology specimen. Cornified cytology is indicative of estrogen secretion. Presence of ovarian follicle is inferred. Measurement of estrogen in serum is not recommended because estrogen is not present in high enough concentrations to allow accurate assay in all cases and because serum estradiol concentrations have not been demonstrated to be well correlated with behavioral and cytologic estrus (Wallace, 1991).
3. Administer either gonadotropin-releasing hormone 50 mcg intramuscularly or human chorionic gonadotropin 500 units intramuscularly when the putative follicle is present to induce luteinization.
4. Draw blood for measurement of progesterone in serum 2 to 3 weeks later. Concentration of more than 2 ng/ml is indicative of luteal function.
5. Perform exploratory laparotomy.

Surgery is the recommended therapy in all cases. There are no estrus-suppressing drugs available for use in cats that are safe or approved in the United States. Surgery should be performed when there is a structure on the remnant

that makes it easy to see (i.e., either a follicle or a corpus luteum). I prefer to perform surgery when luteal tissue is present on the remnant, since the cat bleeds less under the influence of progesterone than under the influence of estrogen and since luteal tissue persists for several weeks after its induction. Remnants may be unilateral or bilateral; they are reported to be bilateral in 27% to 48% of cases (Miller, 1995; Wallace, 1991). Ovarian remnants most commonly are found at the ovarian pedicles, but I am aware of anecdotal and published reports of ovarian remnants found in the omentum, in the subcutaneous space at the linea alba, adhered to the kidney capsule, and on the dorsal body wall. If no obvious remnant is visible, scar tissue at the pedicles should be removed since the remnant may be within this tissue. Any excised tissue should be submitted for histopathology; occasionally ovarian remnants contain neoplastic tissue (Root Kustritz and Rudolph, 2001; Wallace, 1991).

CHAPTER 226

Pregnancy Loss in the Queen

CLAUDIA J. BALDWIN, Ames, Iowa

PREGNANCY LOSS

Confirmation of Pregnancy

Breeding of a fertile queen and tom should result in attainment of pregnancy 70% of the time. Failure to ovulate can be ruled out by measuring serum or plasma progesterone. Pregnancy may be confirmed as early as 2 weeks after breeding. Uterine segmental swellings associated with gestation sacs, fetal poles, heartbeat, and fetal membranes may be seen as early as days 11, 15, 16, and 21, respectively, using ultrasound imaging (Davidson, Nyland, and Tsutsui, 1986). Abdominal palpation may be performed to identify uterine sacculations by day 21, or earlier in cooperative queens, but confirmation of viable fetuses is not possible.

Queens presented during the later phase of expected pregnancy may be subjected to abdominal palpation, abdominal and uterine ultrasound evaluation, and possibly radiographic examination. Uterine segmental swellings may remain easily palpable up until day 35 of gestation, at which time the uterus becomes uniformly enlarged. During the last 7 to 14 days of gestation, the fetuses may be assessed by palpation for movement. Ultrasound evaluation during the later phases of gestation allows more complete assessment of fetal development and heart activity. Radiographic evaluation for presence of developing kittens is best done after day 45. Morphology and development of kittens can be assessed using standards that are widely published. Unfortunately

the majority of queens presented for pregnancy loss will not have had pregnancy diagnosis performed.

A final form of pregnancy loss is the stillborn. This is a well-recognized and much easier event to confirm. It has been reported that stillbirths may occur on an average of 13% of total kitten births.

Historical and Clinicopathologic Findings of Pregnancy Loss

When a queen is presented for failure to produce kittens or for abortion, a careful history should be taken to assess the individual queen and the population. Health maintenance such as vaccination history/protocols, deworming, and serologic tests for feline leukemia virus (FeLV) and feline immunodeficiency virus (FIV) is queried. Dietary management is explored in detail. Breeding dates, the tom used, and the relationship of the tom to the queen are pertinent issues. Past reproductive history and relation to others in the colony are also important. Active and historical illnesses of the queen and the colony are explored. Medications prescribed or used are recorded. Questions are asked about housing of the queen and the typical housing practices of the breeding facility such as sequestration of third-trimester queens, sequestration of the queens and kittens, and other isolation procedures.

The history related to the pregnancy loss may vary considerably. In the event of failure to produce kittens at the

time of expected term pregnancy, there may be no additional history. Other historical findings might include a decrease in abdominal size, weight loss, anorexia, or gastrointestinal signs. When abortion has been observed or is threatened based on characteristic signs of parturition, owners should be questioned about fetal material presented, viability of fetuses, and placentas. The owner may simply have noticed a vaginal discharge that is mucoid, greenish, or serosanguineous. Alternatively the client may present a queen that has produced one or more stillborn kittens.

Physical examination of the queen should be complete, with careful assessment of all body systems by means of observation, auscultation, and palpation. Examination of the reproductive system should include vaginal inspection for discharge or presence of a fetus and uterine palpation. Mammary glands are inspected for development and presence of colostrum or milk. Neonatal, fetal, and placental materials are inspected and handled carefully for further evaluation (e.g., bacterial culture, viral studies, karyotyping). Abnormalities are noted and investigated.

Diagnostic tests may be indicated to ascertain the general health of the queen. Abnormalities in hematology, serum biochemistries, and urinalysis may reflect underlying disease. Assessment of FeLV and FIV status is indicated if not yet performed and reassessed if the colony is not closed. It should be mentioned that a queen develops a dilutional anemia during gestation. Hematologic parameters (red blood cell count, hematocrit, and hemoglobin), along with a decrease in serum protein concentrations, reach a nadir by 8 weeks of gestation and quickly return to normal after queening. Additional diagnostics used to assess pregnancy status include imaging via ultrasound or radiology. Other indicated diagnostics depend on history and physical examination findings.

Confirmation of early embryonic loss before nidation is not possible currently in clinical practice. Early in gestation anechoic gestational sacs may be present, which over time fail to exhibit evidence of fetal structures, suggesting failure of successful nidation or early fetal death. Later in gestation characteristics of fetal death are typified by a variety of findings such as smaller-sized fetus, abnormal placentation, and absence of heartbeat. Fetal resorptions may be seen as focal thickening of the uterus (Yeager and Concannon, 1995). Fetal losses during the pregnancy may be complete or partial; thus as much of the uterus as possible should be scanned. If remaining viable fetuses are identified by ultrasound imaging, prediction of day of parturition may be possible (Beck, Baldwin, and Bosu, 1990). Radiographic imaging may be used to assess presence and location of remaining fetuses, morphologic developmental stage, and signs of fetal death.

DIAGNOSIS AND TREATMENT OF DISORDERS ASSOCIATED WITH PREGNANCY LOSS

There are numerous differential diagnoses for pregnancy loss. The first goal should be to rule out normal pregnancy. Using history, physical examination findings, and imaging, this can be done successfully. On occasion a queen may be presented with a mucoid vaginal discharge near the expected date of parturition. Cytology of this fluid may

reveal mucous and nondegenerate neutrophils without intracellular bacteria. This can be a normal finding. If normal pregnancy is suspected based on examination and testing, the owner should be instructed to isolate and observe the queen. If the queen is thought to have entered stage II of parturition, as evidenced by active straining and normal-sized kittens, the clinician must determine whether normal delivery can occur. If the queen has been presented with one or more stillborn full-term kittens, it is necessary to determine if they might be the result of dystocia and if other fetuses are present. When there is no evidence of pregnancy or if uterine changes suggest disease or mummified or resorbed fetuses or placentation sites in an otherwise healthy young queen, the owner should be counseled. Optimal breeding protocols are discussed, and the client advised to confirm pregnancy after the next breeding. Older queens may benefit from a battery of diagnostic tests (e.g., complete blood count, serum biochemistries, urinalysis, measurement of thyroid hormone [total T_4]) along with ultrasound investigation of the reproductive tract.

Differential Diagnostic Approach to Pregnancy Loss in the Queen

One cannot follow a single differential diagnostic scheme when working through a case of pregnancy loss. Pregnancy loss may be caused by a maternal disorder that has resulted in death of the developing embryo or fetus. This may be caused by disease of a single organ system or one that is multisystemic. Pregnancy loss may also be caused by fetal disorders that cannot be attributed solely to the queen (Box 226-1).

Maternal System Disorders

Maternal system causes of pregnancy loss include both overt and occult disorders. A careful history and clinical evaluation should help identify underlying disease (e.g., renal, cardiac, endocrine, respiratory). Renal disease should be suspected in cats with small kidneys or large and irregular kidneys. Cardiac

Box 226-1

Fetal Disorders

- Developmental
- Genetic/chromosome error

disease should be suspected in cats with murmurs, gallop or irregular rhythms, or poor perfusion or pulse quality. Development of pancreatic disorders, in particular diabetes mellitus, should be suspected in queens with recent onset of polyuria, polydipsia, and weight loss. Each of these systems is of particular interest in purebred cats because polycystic kidney disease, hypertrophic cardiomyopathy, and diabetes mellitus have been associated with the Persian/Himalayan, the Maine coon cat, and the Burmese lines in Australia, respectively. Significant dysfunction of these organ systems could lead to pregnancy complication and loss, as has been documented in studies of Maine coon cats with hypertrophic cardiomyopathy. Other nonbreed-associated congenital or developmental diseases may compromise maintenance of pregnancy. Treatment of these depends on the disease identified.

Primary uterine disease of an inflammatory or infectious nature may be responsible for pregnancy loss or may mimic pregnancy (Fig. 226-1). Inflammatory lesions in the form of cystic endometrial hyperplasia, metritis, or pyometra may be encountered. These may be segmental, likely associated with sites of fetal resorption, or the lesions may be more diffuse, involving one horn or the entire uterus. Clinical signs may be inapparent even when the pathology is sufficient to prohibit nidation and support of pregnancy. In other cases abdominal distention may be the notable sign. When the cervix is open, a vaginal discharge may be present, usually characterized as purulent to serosanguineous. Cytologically either discharge would show an abundance of degenerate neutrophils with intracellular bacteria, suggestive of a septic condition. Numerous bacteria, including normal vaginal flora (e.g., *Escherichia coli*, *Staphylococcus* spp., *Streptococcus* spp., *Mycoplasma* spp.), and pathogens such as *Brucella* spp., *Coxiella burnetii*, and *Salmonella* spp. have been associated with pregnancy loss in the queen. More severe clinicopathologic signs include anorexia, fever, dehydration, polydipsia, collapse, and shock, with leukopenia or leukocytosis and azotemia.

Ultrasound examination of the uterus should assist in diagnosis. Segmental areas of inflammation may not compromise the pregnancy. Metritis or pyometra, with or without pregnancy, requires antibiotics and possibly

intravenous fluid therapy. Additional therapy may include prostaglandin administration in the stable queen or hysterotomy to evacuate the uterine contents when reproductive potential of the queen is important. Alternatively ovariohysterectomy may be the best option (Johnston, Root Kustritz, and Olson, 2001b).

Dystocia must be considered as a cause of pregnancy loss in the queen. There is an increased incidence of dystocia in the purebred cat, and there may be a higher incidence in brachiocephalic and dolichocephalic breeds. Dystocia is often of maternal rather than fetal origin. The queen produces a litter over a highly variable period, although many deliver within hours. After onset of stage II labor, with active straining by the queen the first kitten should be produced within 2 hours, and intervals of straining between kittens should last no longer than 1 hour. If the queen has not been monitored closely, fetal death may occur. When a queen is presented for failure to produce kittens, care should be taken to document the days the queen was bred and previous queen and family history of breeding and problems. Clinical signs related to dystocia may vary. Careful physical examination followed by diagnostic imaging should reveal the presence and size of fetuses. Movement of the kittens on palpation or during ultrasound examination, along with heartbeats, confirms viability. Management of dystocia is based on size of the fetuses and condition of the queen. Medical management may be attempted with oxytocin, provided obstructions to the pelvic canal or oversized and malpositioned fetuses have been ruled out. Once medical management is begun, the queen should be monitored closely, and prompt surgical intervention undertaken if labor is unproductive. There is concern that repeated injections of oxytocin may cause premature separation of the placenta and subsequent death of remaining fetuses.

Other causes of pregnancy loss include uterine torsion and extrauterine mummified fetuses. Clinical signs of uterine torsion can include straining, resembling stage II of parturition; or the queen may present ill with depression, anorexia, and abdominal pain. More severe signs include hypothermia, tachycardia, shock, or collapse. Diagnostic evaluation ideally includes ultrasound imaging that might reveal altered blood flow or congestion. Definitive diagnosis can be made at exploratory surgery. Ovariohysterectomy is the treatment of choice, along with supportive therapy. Extrauterine mummified fetuses, also described as ectopic pregnancy, have been reported frequently in the cat. This condition is a potential cause of pregnancy loss in the queen but is usually an incidental finding. Most commonly the introduction of mummies into the abdomen follows damage to the uterine wall. Treatment for these usually sterile mummies is surgical removal. Careful evaluation of the uterus is advised in the breeding queen to identify uterine scars and anatomic changes that might preclude successful pregnancy or queening in the future.

Failure to maintain pregnancy may stem from insufficient production of progesterone. This should be suspected in the queen that suffers from repeated pregnancy loss. Although this physiologic disorder could occur at any stage of gestation, some theriogenologists suspect that it explains the high incidence of abortion around day 40 or later of gestation in otherwise healthy queens. A history of repeated abortions in a healthy queen would warrant

Fig. 226-1 Photograph of segmental pyometra in a queen that could have been mistaken for normal segmental swelling of the uterus caused by pregnancy. Ovarian pedicle is located in the upper right of the photograph.

frequent monitoring and administration of supplemental progesterone (Johnston, Root Kustritz, and Olson, 2001a). However, progesterone therapy can be problematic since it promotes an environment attractive to bacteria and may cause masculinization of female fetuses.

Maternal Polysystemic Disorders: The DAMNITT Approach

It is often helpful to approach differential diagnoses in a systematic way. The Degenerative, Allergic, Metabolic, Neoplastic, Iatrogenic, Toxic, Traumatic (DAMNITT) scheme has been used for many years in medicine to categorize etiologic diagnoses as: Degenerative, developmental; Allergic, autoimmune (immune-mediated); Metabolic; Neoplastic, nutritional; Iatrogenic, ischemic, idiopathic, inflammatory: infectious, noninfectious, or immune-mediated; Toxic; or Traumatic. Box 226-2 puts this diagnostic approach to use when considering potential causes of pregnancy loss in the queen.

Metabolic

Metabolic disorders can occur in any breed or at any age. Effects of these disorders, if widespread or severe, could threaten the queen's ability to reproduce. A thorough history and physical examination are extremely helpful in diagnosis, along with appropriate diagnostic tests. As presented earlier in the section on Maternal System Disorders, Burmese cats are overrepresented in the population of cats diagnosed with diabetes mellitus in Australia. This is a prime example of breed preponderance of disease that should be considered under metabolic disease. A good example of age predisposition to disease is hyperthyroidism. Older breeding queens (6 years or older) should be assessed for thyroid status before breeding and again if reproductive failure occurs.

Neoplastic

Neoplastic disease that might occur in a breeding queen could certainly lead to pregnancy loss. Neoplasms not only cause dysfunction of the organs involved, but also pro-

mote metabolic changes and possibly fever. These events threaten the affected queen and may impact reproductive performance.

Nutrition

Nutrition is extremely important to reproductive health. The cat is a carnivore and depends on ingestion of meat-based foods to maintain health. Ingestion of taurine is mandatory and is available only in meat. Taurine-deficient rations (<200 ppm of diet) fed to queens for at least 6 months before breeding resulted in decreased reproductive performance, including resorption, abortion, and stillbirths. These effects persisted after feeding a diet with normal amounts of taurine for 6 months (Sturman, 1991). Other work has indicated that restriction results in a postovulatory defect within the first 10 days after implantation (Dieter et al., 1993). Effects on the queens and the live-born kittens were also apparent in these and similar studies. When taking the medical history from clients, careful questioning is necessary. There are many "natural foods," including vegetable-based diets, that are marketed as premium line but may not provide needed nutrition. Education of the client about taurine deficiency and appropriate dietary intake must be ongoing. In my practice discussions of diet are repeated with cat owners and breeders alike.

Inflammatory/Infectious

A number of inflammatory/infectious agents have been incriminated in pregnancy loss in the queen. In addition to those described in the section on Maternal System Disorders involving the uterus and those listed in Box 226-2, one specifically should consider *Brucella* spp. and *Salmonella*. Moreover newly recognized infectious causes are being recognized, through both traditional and emerging diagnostic techniques. The agents most clearly documented are presented in the following paragraphs.

Viral infections, including feline herpesvirus (FHV), calicivirus, feline leukemia, FIV, and feline coronavirus infection may impair reproductive performance in queens and cause fetal death and abortion (see Chapter 224).

Toxoplasma gondii, a protozoan, can also cause pregnancy loss. Infection induced in pregnant queens can cause placentitis and resultant infection in the fetus. Stillborns have been documented. The presence of tachyzoites in stillborn tissues is diagnostic. Clinical signs of toxoplasmosis in the queen are variable. A tentative diagnosis may be made with compatible clinical signs and careful interpretation of serologic titers (both immunoglobulin [Ig]G and IgM). Therapy of toxoplasmosis is described elsewhere in this volume.

Coxiella burnetii, a bacterium known to cause Q fever, has been documented as a cause of abortion in the cat. The cat may not show any signs of disease other than abortion. Infection may occur by tick bites or by ingestion or inhalation. This disease is also important because of the public health aspects. There are numerous reports of people contracting Q fever after exposure to queens (or bitches) during abortion or parturition. Aerosols or fomites are believed to be the route of transmission. Diagnostic tests include antibody tests on serum measured by complement fixation, enzyme-linked immunosorbent assay (ELISA), or fluorescent antibody (FA).

Box 226-2

Maternal Polysystemic Disorders Implicated in Pregnancy Loss in the Queen

- Metabolic
- Neoplastic
- Nutritional
 - Taurine-deficient diets
- Inflammatory/Infectious
 - Upper respiratory disease pathogens
 - Feline leukemia virus
 - Feline immunodeficiency virus
 - Feline infectious peritonitis
 - Parvovirus
 - *Toxoplasma gondii*
 - *Coxiella burnetii*
- Toxicity
- Traumatic

Other infectious agents can threaten pregnancy, especially when they endanger the life of the queen. However, in my experience predictions are not always accurate. An example of this would be a multiparous queen that presented with symptomatic pulmonary blastomycosis and was treated with itraconazole. Any intervention to end the pregnancy was considered too dangerous. Despite the poor prognosis, the queen delivered a live healthy singlet kitten several days after release from the hospital.

Toxicity

Some drugs are known to be teratogenic or to cause pregnancy loss in the queen. Administration of griseofulvin is widely known to produce defects (head, brain, palate, and skeleton) in the developing fetus. Prednisone, a drug that might be needed during pregnancy (e.g., for treatment of asthma, head trauma), can induce premature parturition. It has also been linked to abnormalities in the palate and limbs. Alkylating agents such as cyclophosphamide are embryotoxic in rodents. In general owners should be aware of the known or potential effects of drugs on the pregnancy before administration or prescription.

Trauma

Physical trauma can certainly threaten gestation. In my experience severe trauma such as the queen being hit by a car can produce abortion. This might be because of blunt abdominal trauma, but it can be seen without evidence of this, likely as a result of the physiologic stress imposed by the event. It is also believed that environmental stress can cause pregnancy loss in the queen, possibly from hormonal stress responses, although to my knowledge it has not been documented.

Fetal Disorders

Fetal defects can occur secondary to exposure to a pathogen or substance during a critical phase of development. The magnitude of the defect dictates whether fetal death will occur (Fig. 226-2). It is not uncommon for only some kittens in a litter to display defects. The cause of the disorder may never be detected. Fetal lesions may also relate to chromosomal defects. Lethal gene combinations are known to occur in some feline breeds when bred for particular physical char-

Fig. 226-2 Photograph of a kitten delivered vaginally near term. This kitten was affected by hydrops fetalis, or anasarca.

acteristics. Karyotypes can be investigated by submitting an ear tip from an affected fetus for analysis. Inborn errors of metabolism may also cause pregnancy loss. Urine submission to a genetics laboratory may be useful for confirmation.

THERAPY AND MANAGEMENT

Analysis of the pedigree and screening of breeds with inherited or prevalent organ system disease or dysfunction (e.g., cardiac and renal) before breeding is highly suggested. Maternal disease should be assessed, and appropriate diagnostic tests should follow if abnormalities are found. A mandatory test in my practice is an ELISA for FeLV and FIV.

The queen that is pregnant or one with a threatened loss of pregnancy should be isolated. Sometimes it is necessary to hospitalize the queen, but the addition of this stress must be weighed against the advantages of easier monitoring. In the event of an ongoing or threatened abortion, it is unlikely that medical management will halt the process.

General supportive care (e.g., maintaining adequate hydration by delivery of intravenous fluids) should be offered if it is thought to be of benefit. Treatment of specific diseases may be necessary. The veterinarian should always discuss the potential effect of treatments on the gestating fetuses. The owner will then need to decide whether the queen or the litter is of greatest value. In general I do not attempt to disrupt a pregnancy when treating a specific medical condition since this may threaten the queen more than abortion or parturition. When viral disease is highly suspected, treatment with antiviral drugs might be considered. These drugs have been studied primarily in association with FeLV, FIV, and FHV-1 infection. I am not aware of any studies that assess their effect on pregnancy in the queen.

For future breedings serial ultrasound examinations may be useful if a cause for pregnancy loss has not been identified. Measurement of progesterone concentrations may also be advisable. Use of a different tom, not closely related to the last, is usually recommended. On occasion a repeat breeding is necessary to determine if results of the unsuccessful pregnancy can be duplicated. Recently a gene for miscarriage has been reported in mice. With the feline genome having been sequenced, much more will soon be learned about the genetic basis of specific medical conditions. A mutation has been identified for autosomal dominant polycystic kidney disease (PKD 1) and the breeds affected have expanded. As no homozygous cats have been identified, it is thought that this mutation will result in embryonic death (Lyons et al., 2004). In many Maine coon cats, hypertrophic cardiomyopathy is now known to be an autosomal dominant, single gene defect, with studies of other breeds occurring as well. More recently, 20,285 putative genes in the cat genome have been identified using the genomes of other mammalian species (human, chimpanzee, mouse, rat, dog, and cow) (Pontius, 2007). Genetic testing is now a reality.

CHAPTER 227

Medical Treatment of Benign Prostatic Hypertrophy and Prostatitis in Dogs

KAITKANOE SIRINARUMITR, Bangkok, Thailand

The prostate is the major accessory sex gland in the male dog. It is an encapsulated, bilobed, and bilaterally symmetric ovoid gland that is located caudal to the bladder and circling the proximal urethra. The canine prostate is composed of glandular acini and stromal components. Prostatic fluid is secreted from the glandular acini and excreted through the prostatic duct and prostatic urethra during ejaculation. The normal canine prostate continues to grow from birth to approximately 2 years of age. After 2 years of age the gland is maintained with no further normal growth. The Doberman pinscher and the German shepherd are breeds most frequently identified with prostatic diseases.

BENIGN PROSTATIC HYPERTROPHY

Benign prostatic hypertrophy (BPH) is a spontaneous and age-related condition in men and intact dogs. More than 80% of intact dogs over 5 years of age have either gross or microscopic evidence of BPH. The prostate gland of dogs with BPH is symmetrically enlarged and of moderately firm texture when examined by rectal palpation (Krawiec, 1994). Dogs with BPH are predisposed to prostatic cysts, infection, and prostatic abscessation; and the enlarged prostate may compress the descending colon and/or rectum (Johnston et al., 2001). In dogs older than 5 years of age, the overall rate of cell growth, which is modulated by estrogen and dihydrotestosterone (DHT), outpaces the rate of cell death, which is modulated by apoptosis, leading to a gradual increase in prostate size.

Pathogenesis of BPH

The pathogenesis of BPH is not completely known. Testosterone, DHT, estradiol, and some growth factors such as epidermal growth factor, transforming growth factor, keratinocyte growth factor, and basic growth factor are involved in prostatic growth (Lee, Kozlowski, and Grayhack, 1995). DHT, a form of testosterone metabolized by 5 α -reductase enzyme, is a major hormone involved in prostatic enlargement; it enhances growth of both stromal and glandular components (Sirinarumitr et al., 2001). The uptake of DHT by prostatic cells is stimulated by estradiol. Prostatic DHT concentration in dogs with BPH was reported to be approximately two to four times greater than in normal intact male dogs. However, plasma and prostatic testosterone concentration of dogs with BPH were in the normal range.

Diagnosis of BPH

The diagnosis of BPH is based on detection of prostate enlargement without any other prostatic diseases, and affected dogs may or may not show clinical signs of BPH. Prostatic enlargement is diagnosed when prostatic diameter on the lateral radiograph exceeds 70% of the distance between the sacral promontory and the pubis (Weichselbaum et al., 1995). Clinical signs of dogs with BPH include constipation, sanguineous discharge dripping from the tip of penis, blood in the urine or semen, and difficult urination. Straining to defecate may result in perineal hernias. Clinical signs of BPH in Scottish terriers may be more severe than in other breeds. Digital rectal

examination reveals a symmetrically large and firm prostate with no sign of pain during examination (Sirinarumitr et al., 2001). A dog with BPH with a large prostatic cyst may have an asymmetric lobe. Ultrasonographically the prostate gland is usually symmetrically enlarged with parenchyma that is homogenous in echogenicity and either with or without cavitating cystic lesions (Weichselbaum et al., 1995). A prostatic cyst is usually visible as a discrete, hypoechoic lesion within the parenchyma. The volume of prostatic tissue can be predicted using the formula:

$$(1/2.6 [L \times W \times D]) + 1.8$$

where L = the greatest craniocaudal, W = transverse dimension, and D = the dorsoventral length of the prostate measured by ultrasonography (Kamolpatana, Johnston, and Johnston, 2000). Prostatic volume in the dog with BPH is usually greater than 10 ml and is generally 2 to 6.5 times greater than that of normal dogs of similar weight (Sirinarumitr et al., 2001). Bacterial culture of prostatic fluid collected either by ejaculation or prostatic massage in the dog with BPH should yield less than 10^4 colony-forming units (CFUs) of aerobic bacteria per milliliter and no anaerobic bacteria, *Mycoplasma* spp., or *Ureaplasma* spp. Inflammatory cells should not be seen in the seminal fluid sediment. The complete blood count in dogs with BPH is usually normal (Sirinarumitr et al., 2001).

Medical Treatment of BPH

The treatment objectives in dogs with BPH are to decrease the size of the prostate gland and to alleviate signs related to BPH. Castration is recommended for BPH in most dogs. Medical treatment is indicated for breeding dogs or in cases in which the risk of anesthesia or surgery is high.

Finasteride (Proscar, Merck) 5-mg/tablet, at a dose of 0.1 to 0.5 mg/kg (or 1 tablet/dog weighing between 1 and 50 kg) every 24 hours orally is the recommended drug for BPH treatment in dogs (Sirinarumitr et al., 2001). Finasteride is a 5α -reductase inhibitor and blocks production of DHT from testosterone (Kamolpatana et al., 1998). The prostate in dogs with BPH treated with finasteride creates involution of the gland via programmed cell death (apoptosis) rather than necrosis; thus there is no associated inflammatory process (Sirinarumitr et al., 2002). Finasteride significantly decreases prostatic volume and serum DHT concentration by 40% to 50% but does not adversely affect semen quality, libido, or serum testosterone in dogs with BPH. The only effect of finasteride on semen quality is a decrease in semen volume. Clinical signs related to BPH such as constipation or blood in semen abate within 1 to 4 weeks after the onset of finasteride treatment and no other adverse effects have been reported (Sirinarumitr et al., 2001). Both during and after finasteride treatment, dogs with BPH have successfully bred to bitches that subsequently underwent normal pregnancy, gestation duration, and litter size (Ouada and Verstegen, 1997; Sirinarumitr et al., 2001). Dogs with BPH should receive finasteride treatment for 1 to 4 months. Prostate size and clinical signs are significantly decreased at the end of 1 month of treatment in most dogs.

Diethylstilbestrol (0.2 to 1 mg/dog orally [PO] every 2 to 3 days for 3 to 4 weeks) has been reported to reduce the prostatic size. However, the potential side effects of estrogen treatment in dogs include bone marrow suppression with resultant anemia, thrombocytopenia, or pancytopenia. Repeated administration of high doses of estrogen may incite growth of fibromuscular stroma and induce squamous metaplasia of the prostate.

Medroxyprogesterone acetate (3 mg/kg, with a minimum dose of 50 mg, in two subcutaneous injections 4 weeks apart) (Bamberg-Thalen and Linde-Forsberg, 1993) and megestrol acetate (0.55 mg/kg/day PO for 4 weeks) represent other reported medical treatments for BPH in dogs. Approximately 50% of treated dogs showed decreased prostatic size. Potential side effects of medroxyprogesterone acetate treatment included increased appetite, hypothyroidism, diabetes mellitus, testicular degeneration, and decreased serum concentration of testosterone. Flutamide, an antiandrogen (5 mg/kg q24h PO) significantly decreases prostate size, as determined by ultrasonography, within 10 days of treatment. Libido and sperm production were unchanged in male dogs treated with flutamide for 1 year; however, a course of flutamide treatment is expensive (Barsenti and Finco, 1995). Win 49596, an androgen receptor antagonist, and FRI46687, a steroid 5α -reductase inhibitor, also reportedly decreased prostatic size in research dogs. However, neither drug is available commercially.

PROSTATITIS

Bacterial prostatitis is a very common prostate disease in sexually intact male dogs. Most dogs with prostatitis are over 5 years old. The disease can be either acute or chronic in course. Prostatitis is usually caused by ascending infection of normal (aerobic) urethral bacteria into the hypertrophied gland. Dogs with prostatitis may progress to prostatic abscessation. Prostatitis is predisposed by prostatic diseases such as BPH, prostatic cyst, or prostatic neoplasia. *Escherichia coli*, the most common organism, is found in 70% of dogs with prostatitis, followed by *Staphylococcus* spp., *Streptococcus* spp., *Klebsiella* spp., *Proteus* spp., *Mycoplasma* spp., *Pseudomonas* spp., *Enterobacter* spp., *Pasteurella* spp., and *Hemophilus* spp. (Johnston et al., 2000). Infection with anaerobic bacteria or fungi also has been reported.

Clinical Signs

Clinical Signs of Acute Prostatitis

Clinical signs in dogs with acute prostatitis include fever, pain, depression, straining to urinate or defecate, a "stiff-legged" gait, hematuria, and pollakiuria. There may be edema of the scrotum, prepuce, or hind limb. Dogs with acute prostatitis usually show signs of pain during digital rectal examination of the prostate. The prostate is generally symmetric to palpation. Asymmetric enlargement of a lobe may be found in prostatitis abscessation. The gland may have a fluctuant swelling or be firm on rectal examination. Dogs with prostatic abscessation may show signs of septicemia (Johnston et al., 2001).

Clinical Signs of Chronic Prostatitis

Dogs with chronic prostatitis may be infertile and have signs of poor semen quality such as a decrease in percentage motility, although morphologically normal sperm may be evident. If prostatic contraction is painful, dogs may show decreased libido. Chronic prostatitis dogs may show signs of lower urinary tract disease. Prostatic character on digital rectal examination is symmetric, and dogs may or may not show sign of pain during rectal examination (Krawiec, 1994).

Diagnosis of Prostatitis

Prostatitis is suspected based on a history of constitutional illness, clinical signs, results of complete general physical examination, digital rectal examination of the prostate, hematology, and urinalysis. The condition is verified and staged by quantitative bacterial urine, seminal or prostatic fluid culture, cytologic examination of ejaculated semen or prostatic fluid, abdominal radiography, and either retrograde urethrocytography or prostatic ultrasonography. Complete blood count in dogs with prostatitis shows regenerative leukocytosis. Urine may contain blood, bacteria, or leukocytes. Prostatic fluid collected by ejaculation or prostatic massage contains significant numbers of inflammatory cells, and quantitative culture of prostatic fluid contains bacteria greater than 10,000 CFUs/ml (Johnston et al., 2001). Prostatic abscesses detected by ultrasonography are visible as discrete hypoechoic or anechoic lesions with or without distant enhancement. Prostatic abscess or cyst cannot be differentiated solely by using ultrasound.

Treatment of Prostatitis

Treatment strategies for canine prostatitis center on an appropriate antimicrobial therapy with other supportive treatments. The clinician may consider a combination treatment to decrease prostatomegaly caused by BPH; either antiandrogen (finasteride) or castration is appropriate. Antimicrobial therapy is based on the result of sensitivity of bacteria cultured from prostatic fluid collected by ejaculation or prostatic massage. The antimicrobial drug should diffuse into prostatic fluid. Antimicrobial drug for prostatitis treatment should have high lipid solubility, low protein binding in plasma, and low pK_a allowing diffusion of the nonionized form of the drug across the lipid prostatic membrane (Dorfman and Barsenti, 1995). Antimicrobial drugs that are highly lipid soluble include trimethoprim-sulfa, chloramphenicol, and the fluoroquinolones enrofloxacin and ciprofloxacin. These drugs are all effective against aerobic bacterial infection (Johnston et al., 2001; Dorfman and Barsenti, 1995). Fluoroquinolones are also effective against *Mycoplasma* spp. infection, and chloramphenicol is effective against anaerobic infection. Treatment with a specific antimicrobial drug should be continued for at least 4 to 6 weeks. Before treatment the size of prostate or abscess should be measured and recorded. Complete blood count, blood chemistry profiles, and prostatic ultrasonography should be evaluated before and 2 to 3 weeks after antimicrobial therapy and again once antibiotic is withdrawn. If the selected antibiotic is appropriate, clinical signs are relieved, prostatic abscessation is reduced in size or eliminated, and total

white blood cell count is decreased. Prostatic fluid should be recultured at 7 to 10 days and again at 30 days once antibiotic treatment is concluded to ensure clearance of the bacterial infection. Some dogs with prostatitis may require antibiotic therapy of more than 2 months. Adverse effects or toxicities of chronic antibiotic therapy should be considered by the attending veterinarian. A combination treatment of a selective antibiotic and antiandrogen (finasteride) therapy is more successful for treating prostatitis than antibiotic treatment alone. Castration should be considered in canine prostatitis, especially if the disorder is recurrent or when an intact male is not a breeding dog. Before castration, prostatitis dogs should be retreated with antibiotics until signs of prostatitis are resolved.

I have not found surgical or needle drainage of prostatic abscesses to be necessary. Long-term antibiotic therapy (up to 4 months) and antiandrogenic treatment may be necessary to achieve medical resolution. Prostatic ultrasonography and complete blood count should be performed every 2 to 4 weeks to monitor resolution of the abscess, and treatment should continue until the abscess is no longer visible ultrasonographically. After resolution of the prostatic abscess, castration or finasteride treatment should be used to further decrease prostate size and likelihood of recurrence.

Aspermia/Oligozoospermia Caused by Retrograde Ejaculation in the Dog

STEFANO ROMAGNOLI, *Legnaro, Italy*
GIOVANNI MAJOLINO, *Collecchio, Italy*

A retrograde flow of small quantities of spermatozoa into the bladder is a normal event. This may occur during ejaculation, as well as during sexual rest, and has been documented in many species, including bull, ram, cat, dog, and humans (Dooley et al., 1986, 1990, 1991; Pineda and Dooley, 1991). Since testicular sperm production is a continuous event, sperm leave the testis at a constant rate and move through the caput and corpus epididymis as a result of rhythmic contractions of the smooth-muscle epididymal wall. Although the cauda epididymis is normally quiescent, occasional smooth-muscle contractions at this level promote voiding of spermatozoa and epididymal fluids into the urethra during periods of sexual rest, which explains the common finding of spermatozoa in the urine sediment of both humans and domestic male animals (Doxey, 1983; Bush, 1991). In dogs examination of the urine sediment has been suggested as a way of establishing that spermatogenesis is occurring (Ferguson and Renton, 1987).

A retrograde flow of large quantities of spermatozoa back into the bladder is an abnormal event, which may occur during ejaculation as a result of a partial or complete absence of bladder neck contraction during semen expulsion. When this happens, the bladder becomes the least resistant pathway for seminal fluids coming from the urethra. The ejaculate is scant or absent, and spermatozoa can be retrieved in large quantities from the bladder. Following erection and pelvic thrusting, a normal dog produces an ejaculate composed of 0.5 to 2.5 ml of presperm and sperm-rich fraction and 4 to 45 ml of prostatic fluid fraction, depending on testicular volume. A complete lack of ejaculate or production of minute quantities of ejaculate may indicate that semen was totally or almost totally diverted from its normal ejaculatory path and flowed into the bladder. Retrograde ejaculation is defined as a retrograde flow of the majority of or all the semen into the bladder, resulting in no semen (aspermia) or minute quantities of semen (oligozoospermia) being ejaculated antegradely.

Aspermia in the dog may be caused by sexual immaturity, pain, psychologic factors, drug therapy, diseases of the reproductive tract such as *Brucella canis* and *Pseudomonas aeruginosa* infection (George, Duncan, and Carmichael, 1979; Janza et al., 1988, Johnston, Root Kustritz, and Olson, 2001), or sympathetic neuropathy either idiopathic

or secondary to diabetes mellitus or spinal cord injury. Oligozoospermia in the dog may be idiopathic or caused by season; unilateral Sertoli cell tumor; prostate disease, orchitis and epididymitis caused by *B. canis*, *E. coli* mycoplasma, and other aerobic organisms; immune-mediated orchitis; or use of drugs such as steroids, chemotherapeutic agents, ketoconazole, and gonadotropin-releasing hormone agonists/antagonists (Jonhston, Root Kustritz, and Olson, 2001). An oligozoospermic ejaculate is characterized by a low number of spermatozoa diluted in a very small quantity or in a normal quantity of prostatic fluid. However, presence of a normal quantity of prostatic fluid in the ejaculate generally rules out failure of bladder neck closure. Therefore retrograde ejaculation should be suspected whenever an aspermic or oligozoospermic (0.1 to 0.3 ml total volume) ejaculate is produced following normal erection and pelvic thrusting.

ANTEGRADE EJACULATION

The ejaculatory process consists of three distinct events: *seminal emission* (the deposition of seminal fluid originating from the vasa deferentia and the prostate into the prostatic urethra), *bladder neck closure* (caused by contraction of the dorsal segment of the bladder neck), and *seminal expulsion* or *ejaculation* (the passage of seminal fluids through the urethra followed by their expulsion through the external urethral orifice). Once erection is achieved, peristaltic contractions in the epididymis and vas deferens caused or increased by oxytocin start to convey spermatozoa and seminal plasma into the prostatic urethra, causing an increase in urethral pressure. Such an increase (helped by contraction of the smooth muscle cell component of prostatic lobules) forces prostatic fluid into the prostatic urethra (Shafik et al., 2006), which in the adult male dog has a rich elastic layer in the submucosa and is almost devoid of smooth muscle (Cullen, Fletcher, and Bradley, 1981). Further increase in intraurethral pressure occurs when the erectile tissue of the urethra expands, thereby reducing the urethral lumen. When the intraluminal pressure of the vasa deferentia and prostatic urethra reaches maximum, a relaxation of the striated musculature of the pelvic urethra occurs, which allows expulsion of seminal fluid outside through the pelvic and penile urethra (Hovell et al., 1969). Seminal emission is powered

by recoil of elastic fibers in the prostatic urethra (Cullen, Fletcher, and Bradley, 1981). At this point a striated urethral muscle peristaltic wave cycle sets in motion, which completes the ejaculatory process.

The bladder neck plays an important role during seminal emission and seminal expulsion, preventing a retrograde flow of semen into the urinary bladder. During the ejaculatory process the canine bladder neck shows periods of intense contractile activity followed by phases of relaxation (Koraitim et al., 1977); the duration of each relaxation phase decreases gradually until a continuous contractile momentum of the dorsal segment of the bladder neck (the ventral segment of the canine bladder neck is mainly concerned with continence and voiding) occurs toward the end of the ejaculatory process. When the dorsal segment of the bladder neck is relaxed (during sexual rest and in-between urethral muscle peristaltic contractions early in the ejaculatory process), semen may flow back into the urinary bladder following the least resistant pathway. If the bladder neck contracts at ejaculation, the urethra becomes the least resistant pathway through which semen is propelled outside.

The ejaculatory process is coordinated by sympathetic and parasympathetic neural activity. The brain facilitates or inhibits sexual function by mediating and integrating reproductive motivation and reproductive behavior with other types of social behavior, whereas the spinal cord integrates visceral and somatic stimuli, evoking the reflexes of erection and ejaculation (Hart, 1974). Spinal reflexes occurring during the ejaculatory process in the dog are listed in Box 228-1.

Rationale for Treatment of Retrograde Ejaculation

The fact that the canine vas deferens, epididymis, prostate, and bladder neck are primarily under sympathetic nervous system control gives to sympathomimetic agents a pivotal role in the pharmacologic treatment of retrograde ejaculation. Following administration of sympa-

thomimetic drugs, the canine epididymal and prostatic tissue displays phases of rhythmic contractions (Arver and Sjostrand, 1982; Noguchi et al., 2008). Contraction and relaxation of the vas deferens are mediated by α - and β -adrenoceptors, respectively (Trachte, 1987; Noguchi et al., 2008). The use of an α -adrenoceptor agonist together with a β -adrenoceptor antagonist has been proposed to increase spermatozoal output in the dog (Rath, 1983). Administration of xylazine (an α_2 -adrenoceptor agonist) in the dog increases contractility of the vas deferens and epididymis and decreases urethral pressure, inducing non-ejaculatory displacement of canine spermatozoa in the bladder (Dooley et al., 1990). Selective α_2 -adrenoceptor antagonists such as yohimbine or rauwolscine have a stimulatory effect on ejaculation in dogs when administered at low doses (both drugs have been used at 0.01 to 0.1 mg/kg intraperitoneally); when used at this dose, yohimbine can prevent in the dog the decrease in the amount of ejaculate produced by repeated semen collections (up to eight times a day), whereas a high dose (1 mg/kg) decreases the amount of ejaculate produced (Yonezawa et al., 1990).

The canine bladder neck has a rich cholinergic and adrenergic innervation. Cholinergic stimulation produces gradual contraction of the neck, as well as of the whole bladder (occurring during micturition); whereas adrenergic stimulation occurring at ejaculation causes contraction of the neck and relaxation of the body of the bladder (Raezer et al., 1973). Administration of the α -adrenoceptor antagonist phentolamine 5 to 10 minutes before semen collection may increase the retrograde flow of canine spermatozoa into the bladder up to 2.5% of the total ejaculate (Schnee, 1985). Administration of the β -receptor agonist clenbuterol before semen collection increased the number of spermatozoa found in the bladder of two of three dogs, whereas administration of the α -receptor agonist midodrine was able to counteract the effect of clenbuterol (Hahmann, 1988).

Sympathomimetic agents such as ephedrine, pseudoephedrine hydrochloride, phenylpropanolamine, and imipramine are generally used (alone or in combination) to treat human retrograde ejaculation (Lipshultz, McConnell, and Benson, 1981; Lange et al., 1983). Treatment protocols using sympathomimetic drugs reported in the dog include phenylpropanolamine (3 mg/kg orally [PO] twice daily) and pseudoephedrine hydrochloride (3 to 5 mg/kg PO three times daily or 3 and 1 hours before breeding/semen collection) (Romagnoli et al., 1992; Root, Johnston, and Olson, 1994; Johnston, Root Kustritz, and Olson, 2001).

Success of treatment depends on etiology. Retrograde ejaculation can be the result of *anatomic causes* (iatrogenic defects following bladder or prostate surgery), *neuropathic causes* (diabetes; prolonged treatment with ganglionic or adrenergic blocking drugs such as methyldopa, phenoxybenzamine, guanethidine, reserpine and phentolamine; or following retroperitoneal lymph node dissection for testicular cancer) or *psychologic factors* (pain, fear of new environment, uneasiness when a manual semen collection is attempted for the first time, or lack of interest in the bitch). Treatment of retrograde ejaculation from anatomic causes generally is unsuccessful. Humans with lack of antegrade ejaculation caused by diabetes or

Box 228-1

Spinal Reflexes Occurring in the Dog During the Ejaculatory Process

Type 1: A very intense ejaculatory reflex occurring soon after intromission and lasting 15-30 seconds characterized by pelvic thrusting, alternate stepping of the hind legs, rapid engorgement of the erectile penile tissue, and expulsion of the sperm-rich fraction of semen.

Type 2: A less intense ejaculatory reflex lasting 10-45 minutes characterized by rhythmic contractions of the bulbospongiosus muscle and ejaculation of prostatic fluid accompanied by rhythmic contractions of the anal sphincter.

Type 3: Pelvic thrusting provoked by manual stimulation of the glans penis, often accompanied by partial erection without ejaculation.

Type 4: Lordosis and strong extension of the hind legs when the distal end of the penis is touched.

retroperitoneal lymph node dissection for testicular cancer are treated successfully with sympathomimetic drugs; whereas in the case of chronic therapy with ganglionic or adrenergic blocking drugs, cessation of treatment reestablishes an antegrade ejaculation. In men the use of drugs influencing libido such as human chorionic gonadotropin is reported as effective in the case of retrograde ejaculation caused by psychologic factors (Lipshultz, McConnel, and Benson, 1981).

Incidence of Retrograde Ejaculation in the Dog

In the dog retrograde ejaculation has been observed by researchers while doing experiments on male reproductive physiology (Ferguson and Renton, 1987; Dooley et al., 1990; Pineda and Dooley, 1991; Dooley et al., 1991). In addition, spontaneous (nondrug-induced) retrograde ejaculation causing aspermia has been reported in a 4-year old German shepherd (Meinecke, 1976) and in a 7-year English cocker spaniel (Romagnoli et al., 1992), and oligozoospermia has been reported in a 19-month-old Labrador retriever (Root, Johnston, and Olson, 1994). The German shepherd had never fathered a litter of pups before referral, and its libido was normal; it showed a complete lack of ejaculate, and a high number of 30% progressively motile sperm were found in the bladder following an attempt at semen collection. Pharmacologic treatment was not attempted in this dog (Meinecke, 1976).

The English cocker spaniel had previously fathered two litters of six and five puppies and had been treated with megestrol acetate because of behavioral problems for about 8 months, during which time it progressively lost his libido. Several months following cessation of therapy the dog was examined for breeding soundness because of infertility. Its blood glycemia and libido were normal; but on semen collection performed various times over a 2-month period it consistently failed to produce any ejaculate, whereas large numbers of 50% to 70% motile spermatozoa were retrieved in voided urine samples (Fig. 228-1). Oral pseudoephedrine

Fig. 228-1 Smear of the sediment of a voided urine sample of a 7-year-old English cocker spaniel dog following an aspermic ejaculation. A cross-sectioned hyaline cylinder can be observed in the upper half of the picture (Harris-Schorr, 400 \times).

failed to induce an antegrade ejaculation when administered at a dose of 5 mg/kg three times at 8-hour intervals, whereas a normal antegrade ejaculation was obtained when pseudoephedrine was administered at a dose of 3 mg/kg 3 and 2 hours before semen collection. During this time the dog produced a litter of three normal pups using semen collected with a pseudoephedrine pretreatment, and several months later it regained its capability to ejaculate antegradely without pseudoephedrine pretreatment (Romagnoli et al., 1992).

The Labrador retriever had bred two bitches, neither of which had produced a litter. On semen collection with an estrous teaser bitch it ejaculated 1 ml of semen containing 1 million spermatozoa with 50% progressive motility. Hypothyroidism was diagnosed based on decreased resting serum levels of triiodothyronine and thyroxine. On treatment with pseudoephedrine hydrochloride at the dose of 4 mg/kg given orally 1 and 3 hours before semen collection, the dog produced 1.5 ml of semen with 250 million spermatozoa with 60% to 70% progressive motility. One month later the hypothyroidism had been solved, but the dog would ejaculate normally only following a pseudoephedrine treatment. This dosage allowed collection of a good-quality semen sample with which a litter of 5 puppies was produced. A cause-and-effect relationship between hypothyroidism and retrograde ejaculation could not be established in this case (Root, Johnston, and Olson, 1994).

We have observed retrograde ejaculation causing oligozoospermia in one English setter and aspermia in one German shepherd (data not published). An 8-year-old previously fertile English setter was referred with a history of infertility observed over the last 2 years. On the first two semen collections with estrous teaser bitches the dog showed good libido, displaying pelvic thrusting, alternate stepping on the hind limbs, and anal contractions and lordosis but produced only 0.0 and 0.1 ml of semen (the latter with 70% progressively motile spermatozoa), respectively. A 15-ml voided urine sample collected at the second semen evaluation showed a total count of 45 million 70% progressively motile spermatozoa. The dog was treated with pseudoephedrine at the dose of 5 mg/kg 4, 1, and 0.5 hours before semen collection and produced on two different occasions 1 week apart 0.3 and 1 ml of normal semen with 70% progressively motile spermatozoa, respectively; the owner was instructed to administer pseudoephedrine at home using this dosage before natural breeding, and the dog produced a normal litter. A 4-year-old German shepherd was referred for having never produced a litter of puppies. The referring veterinarian had attempted semen collection on two different occasions, always in the presence of estrous teaser bitches: on both instances the dog showed normal libido, pelvic thrusting, alternate stepping of the hind limb, and anal contractions but produced no ejaculate; a voided urine sample collected at the second semen evaluation performed by the referring veterinarian showed a low concentration of dead spermatozoa. When semen was collected subsequently in the presence of an estrous bitch, the dog again showed a normal libido and produced no semen; a voided urine sample showed large numbers of live and progressively normal spermatozoa. The owner was instructed to administer pseudoephedrine before a natural breeding at home, but the dog died of trauma shortly thereafter.

Clinical Considerations for Diagnosis and Treatment

When performing a breeding soundness evaluation in the dog, it is important to carefully observe behavior during semen collection or natural breeding. A normal dog in a comfortable environment consistently displays types 1 and 2 spinal reflexes, indicative of ejaculation such as pelvic thrusting and alternate stepping on the hind legs, followed by rhythmic anal contractions. Pelvic thrusting is generally displayed both during natural breeding and semen collection, whereas alternate stepping on the hind legs is often observed only during natural breeding. If rhythmic contractions of the anal sphincter (indicating contractions of bulbospongiosus muscle causing ejaculation of prostatic fluid) are not preceded by pelvic thrusting, ejaculation may be incomplete (only prostatic fluid) or absent. If both types 1 and 2 spinal reflexes are displayed and no semen is collected or no spermatozoa are observed in a vaginal smear following breeding, evaluation of a voided/cystocentesis urine sample looking for large numbers of live, normal spermatozoa is warranted.

Although considered a rare event, retrograde ejaculation in the dog could be more frequent than expected. Inadequate penile manipulation during canine semen collection may increase the percentage of retrograde flowing spermatozoa from 0% to 60% (Schnee, 1985). Also, lack of interest in the bitch or fear of a new environment could be responsible for lack of or insufficient spinal reflexes, leading to insufficient activation of the sympathetic system, thereby causing retrograde ejaculation. The role of diabetes mellitus, urinary/prostatic surgery, or retroperitoneal lymph node dissection in the pathogenesis of canine retrograde ejaculation has not been investigated. When diagnosing oligozoospermia (with minute quantities of semen) or aspermia, clinicians should rule out retrograde ejaculation by collecting a voided/cystocentesis urine sample and looking for large numbers of live, normal spermatozoa.

Human spermatozoa ejaculated retrogradely into the bladder can be retrieved and used for artificial insemination provided that the urinary environment is alkaline (pH >7.0) and with a low osmolality (200 to 300 mOsm/kg of water). This is achieved by having the man drink large amounts of water and take sodium bicarbonate on the day before and the day of semen collection. Voided or catheterized urine is centrifuged at 300 to 500g, the sperm pellet resuspended in a semen extender, and inseminated. Although such a procedure has been attempted in the dog without success (Post et al., 1992), more clinical research is needed on this topic.

Sympathomimetic agents deserve more attention from clinicians because of their specific action on sperm production and output in the dog. Yohimbine appears to be able to increase sperm output in the dog, a claim that, if substantiated by clinical reports, could open new interesting avenues for the treatment of oligozoospermic dogs. In the treatment of human retrograde ejaculation the use of some of the sympathomimetic agents is characterized by development of tachyphylaxis (caused by depletion of norepinephrine stores at the terminal nerve endings), a feature that is less common when using the α -sympathomimetic drug phenylpropanolamine. The occurrence of tachyphylaxis following treatment with sympathomimetic drugs

has not been extensively studied in small animals; however, tachyphylaxis due to ephedrine and phenylpropanolamine is reported to occur in the cat and dog, respectively (Cowan et al., 1963; Weiss and Ellis, 1994). Adverse effects of sympathomimetics on heart rhythm and blood pressure should be appreciated.

CHAPTER 229

Intermittent Erection of the Penis in Castrated Male Dogs

MARGARET V. ROOT KUSTRITZ, *St. Paul, Minnesota*

Intermittent erection of the penis in castrated male dogs primarily is a behavioral problem. It should be differentiated from paraphimosis, which is inability of the male to replace the nonerect penis in the prepuce, and priapism, which is persistent erection of the penis.

Erection is a nonhormonal event, mediated neurologically by the parasympathetic nervous system via the pelvic nerve and psychogenically by cerebral centers that augment neurologic activity. Therefore intermittent erection of the penis may occur in any male dog, regardless of sexual status, age, or history of sexual activity.

Onset of intermittent erection of the penis is variable. Some dogs exhibit this behavior throughout their lives, whereas others may show no such behavior until years after castration. Clinical signs vary from apparent inattention to the erect penis, to occasional licking of the erect penis, to apparent pain with frantic licking and biting at the erect penis and prepuce.

Physical examination reveals a penis that is readily extruded and replaced within the prepuce and that has no visible lesions or inflammation other than that caused by self-trauma. In one report of six intact male dogs with idiopathic chronic penile protrusion, all had drying or mild erythema of the tip of the penis and no other clinical signs (Papazoglou, 2001).

Treatment is geared toward eliminating any situation causing sexual arousal or excitement that can be correlated with episodes of penile erection. In many cases

there is no identifiable underlying cause, and ignoring the behavior may be the best behavioral therapy. Owners tend to overreact to penile erection, giving the dog a large positive reinforcement whenever it occurs. Tranquilizers or antipsychotic drugs may be beneficial in dogs that damage the penis or prepuce from frantic licking and biting. Progestogens may be beneficial, perhaps because of their anxiolytic and antiinflammatory properties. Examples include megestrol acetate (Ovaban, Schering-Plough; 0.5 mg/kg once daily orally [PO] for a maximum of 30 days or 2 mg/kg once daily PO for 8 days), medroxyprogesterone acetate (2.5 mg/kg subcutaneously [SQ] every 5 months for a maximum total length of 1 year of treatment), and proligestone (10 mg/kg SQ for a maximum of four injections with a 3-month interval between the first two injections, a 4-month interval between the second and third, and a 5-month interval between the third and fourth). Side effects of progestogen therapy include polyphagia and depression, as well as predisposition to diabetes mellitus and perhaps mammary neoplasia.

Methods and Availability of Tests for Hereditary Disorders of Dogs

EDWARD E. (NED) PATTERSON, *St. Paul, Minnesota*

Study of the biochemical and physiologic bases of canine heritable disorders over the last 10 to 20 years has identified mutations responsible for a number of diseases. The progress of the canine genome maps and the recent publication of the canine genome sequence (Lindblad-Toh et al., 2005), coupled with comparative data from human genome research, have led to the recent discovery of the molecular basis of additional canine inherited disorders. There are now more than 370 recognized inherited diseases in dogs (Patterson, 2000), but in many the biochemical or molecular basis is not yet identified. With additional research and emerging technologies, the number of available tests will grow exponentially in the near future. A working knowledge of the basic methods and availability of such tests will increasingly be an important part of the knowledge base of the small animal veterinarian. Biochemical, direct mutation, and genetic linkage tests are the three major categories of inherited disease diagnostic tests.

SCIENTIFIC BASIS OF THE TESTS

At present, there is no standardization of the basis, methods, techniques, or quality control of inherited disease testing for small animals. In addition, there is no oversight or accreditation of animal genetic testing laboratories and companies. There is a need for regulations and guidelines for small animal genetic testing. Until these are enacted, veterinarians submitting samples for canine genetic disease testing need to evaluate each test individually to determine its accuracy and reliability. A basic knowledge of the methods of the test and an evidence-based approach to its evaluation are important to guide decisions about when to use a specific test. Criteria for molecular genetic testing should be similar to those for any diagnostic medical test. Within a reasonable amount of time after development, the data and results of the test should be published in a peer-reviewed scientific journal. Ideally the test should be verified independently by an outside group. Any test that has not had peer-reviewed scrutiny should be used cautiously. Short of a peer-reviewed publication, all available evidence and data should be very critically evaluated. For some of the currently available tests, only patent information is available at this time, and this information can be reviewed through the U.S. patent website (www.uspto.gov/main/patents.htm). In some cases companies offering tests are awaiting resolution of intellectual property issues.

BIOCHEMICAL TESTS

Biochemical tests for inherited disorders in dogs have been available for many years and will continue to play a very important role in diagnosis of inherited disorders in which the chromosomal location or gene for the defect has not yet been identified. Most biochemical tests require only a simple blood or urine sample. Biochemical tests are also necessary to help evaluate newly developed molecular genetic tests, especially those lacking documentation or presenting controversy. Examples of some of the currently available biochemical tests include those for mucopolysaccharidosis, Fanconi syndrome, erythrocyte osmotic fragility, methylmalonic aciduria, cystinuria, urinary acids, urinary amino acids, urinary carbohydrates, urinary glycosaminoglycans, urinary oligosaccharides, and other inborn errors of metabolism performed at the University of Pennsylvania School of Veterinary Medicine (PennGen) (Table 230-1). Factor assay tests for von Willebrand disease and other inherited coagulopathies are performed at a number of veterinary diagnostic laboratories. In many cases biochemical tests are the best estimate of the genetic status of an individual (affected, carrier, or clear). However, test results can fall into overlapping categories, causing problems with classification and definition.

DEOXYRIBONUCLEIC ACID-BASED TESTS

The dog has 39 chromosome pairs, with one of each pair inherited from each parent. There is complimentary base pairing of adenine-thymine and cytosine-guanine nucleotide representing the building blocks of deoxyribonucleic acid (DNA). Restriction enzymes cut DNA at specific, short sequences of DNA. There are many genetic markers that do not code for messenger ribonucleic acid or proteins (noncoding markers). These markers are interspersed throughout all chromosomes, and there are a number of noncoding markers near every gene. The markers tend to be variable among individuals because changes in the nucleotides do not have any known functional effect. Many of the markers currently used in canine genetic studies are repeats of nucleotides (e.g., CA repeated 10 to 30 times). The resulting different lengths of DNA can be detected on a gel because the fragments migrate in an electrical field in inverse proportion to their size. The different lengths of the marker are called different alleles, just as different blood types represent different alleles of a coding gene. Single nucleotide polymorphisms (SNPs)

Table 230-1

have another type of genetic marker, and canine SNP arrays that can genotype thousands of SNP markers for one individual are just becoming commercially available.

A genetic marker can be strongly associated or linked with a disease gene if it is very close to a gene and the marker has more than one allele. The farther a marker is from a gene on the same chromosome, the more likely recombination is to have occurred during meiosis. The percentage of time a marker and gene have recombination between them is termed the *recombination fraction*. For a marker to be potentially useful as a screening genetic test, there generally needs to be a recombination fraction of 5% or less. Fig. 230-1 illustrates marker and gene linkage and recombination. Understanding that a marker allele is linked to a disease is probably the most difficult concept preventing an understanding of published chromosomal locations of causative genes and molecular genetic disease testing.

Direct mutation tests detect DNA sequence differences in the specific causative gene. A genetic marker test detects a marker allele linked with a mutation in a nearby, unknown gene. For either type of molecular genetic test only a small DNA sample obtained from a special cheek swab kit or an ethylenediaminetetraacetic acid whole-blood sample is needed. Instructions for the type of sample are easily found on the laboratory website or via phone contact. These tests can be performed at any age after weaning and need be done only once in a lifetime. Laboratories should always run positive and negative controls for all

Fig. 230-1 Genetic linkage of a marker A and gene G, and recombination between G and marker B. The left portion shows two homologous chromosomes with gene G and markers A and B. G refers to the normal gene allele and g refers to the mutated gene allele. A(2) is marker A allele 2, and A(1) is marker A allele 1. The left side shows the A(1) and B(1) marker alleles linked with the mutation g. The middle shows a recombination event during meiosis, and the right side shows that marker A, which is very close to the gene, still has allele A(1) linked with the mutation g. However, marker B now has changed to allele B(2) linked with mutation g as a result of the recombination event. A marker must be very close to the gene with a low recombination frequency and with specific population dynamics of the alleles to be a reliable screening test.

molecular genetic tests to ensure accuracy and reliability. A list of the major canine molecular genetic testing laboratories can be found in Table 230-1. This is not an inclusive list since new laboratories are frequently established. Cost for molecular genetic tests currently range from about \$40 to \$260 for a single test on one individual.

Direct Mutation Tests

The testing procedure for a direct mutation test is straightforward and relatively simple. Depending on the exact mutation, there are several different detection methods. For many of the tests the specific DNA in the area of the specific known mutation is polymerase chain reaction (PCR) amplified and then cut with a restriction enzyme that differentially cuts or does not cut the normal and mutated sequences. The restriction enzyme products are then size separated on a gel, and the different-sized products can be categorized into normal, heterozygous (carrier for a recessive disease or affected for a dominant disease), and homozygous-affected categories. See Fig. 230-2 for a hypothetical example that illustrates direct mutation testing for a recessive disease. It is very important to realize that each specific test checks for only one mutation in the gene. Table 230-2 contains a list of the direct mutation tests that are currently available.

Fig. 230-2 Gel electrophoresis results for a hypothetical direct mutation test for a recessive disease. The normal and mutation polymerase chain reaction sequence products are both 100 base pairs (bp) long. They differ in a C to A substitution in the second nucleotide shown. A restriction enzyme cuts the mutation sequence between the G and A into a 60- and a 40-base pair fragment, but does not cut the normal product. The fragments are size separated and visualized on a gel. The results unequivocally categorize individuals into clear, carrier, or affected for this one specific mutation. This does not test for other mutations in the same gene. Laboratories should always run positive and negative controls for all molecular genetic tests.

AD, Autosomal-dominant; AD(P), autosomal-dominant with partial penetrance; AR, autosomal-recessive; NDY, no data yet: no publicly available data at present to my knowledge beyond that indicated on the website; patent, patent which can be viewed on U.S. patent website; PBL, peer-reviewed publication; Un, unknown; XL, X-linked-recessive.

Direct mutation tests can be virtually 100% accurate if there is a strong founder effect within the breed, but another mutation in the same gene or a different gene causing the disease is always a possibility in some percentage of the cases. (All information in this table is deemed reliable at the time of writing, but I do not guarantee its accuracy or completeness; see the individual laboratory for full details).

Once a causative mutation for an inherited disorder has been well documented, a direct mutation test can be nearly 100% accurate if the disease in the breed has been passed on by a popular breeding animal. Many genetic diseases in the dog are recessive because of this founder effect (Ostrande, Galibert, and Patterson, 2000). In humans with recessive diseases, affected individuals often

are compound heterozygotes (i.e., they have two different mutations of the same gene causing the disease). On the other hand, affected dogs often have two identical copies of the same mutation passed on from the founding individual through both their sire and dam lines. If the founder effect is very strong within a breed for a particular disease and no other similar forms of the disease are

caused by a different mutation in the same gene or other genes, a direct mutation test is highly accurate. However, one must always consider the possibility of a new (de novo) mutation occurring in the same gene. These are different from the primary mutation within that breed and create the possibility of heterogeneity of an identical-appearing disorder caused by a different gene. Among breeds the specific mutations are sometimes exactly the same, as in some instances of type 1 von Willebrand's disease. Other times the mutations are breed specific as with the three different mutations for narcolepsy in the hypocretin receptor gene of Doberman pinschers, Labrador retrievers, and dachshunds (Hungs et al., 2001).

Genetic Linkage Tests

A genetic linkage test is based on linkage between a genetic marker allele and a disease. There are two major ways to prove linkage. The first is a family linkage study in which marker alleles are tracked through generations of affected families in a breed to determine if the marker allele cosegregates with the disease. When statistically significant linkage is found through a significant log of odds score of 3 or greater, this is direct evidence of the causative mutation residing on the chromosomal segment containing the marker. The other major method of showing association between marker allele and a disease is by a linkage association study, which is done by testing markers on a group of affected individuals versus a matched group of normal control individuals. A statistically significant association by chi square or other statistical analysis can identify chromosomal regions that potentially contain the causative gene for an inherited disorder. This type of association of a marker allele and disease is termed *linkage disequilibrium* (Mostoskey et al., 2000) and indicates that one allele of a marker is associated with a disease far more often than would be expected if the marker allele frequencies were in Hardy-Weinberg equilibrium.

Statistical association in linkage studies is not necessarily direct evidence that a gene is in a chromosomal

segment close to the marker. There is always the possibility of confounding variables and false positives. If the association is true, evidence from linkage association studies should be verifiable through family linkage studies. Positive association studies are insufficient evidence for validating a marker linkage test. A genetic linkage test should be used for individuals only when it has been proven through family analysis and strong association in the breed population. See Fig. 230-3 for a hypothetical example of a genetic linkage test done on a family.

Genetic linkage tests are never 100% accurate for all individuals in a breed; therefore they should be considered screening tests only. As previously discussed, depending on population dynamics and other factors, a direct mutation test can sometimes be very close to 100% accurate and therefore is considered the definitive test. The accuracy of the genetic linkage test depends on the recombination fraction between the marker and the gene and the population dynamics of the breed. One specific allele of the linked marker is most often associated with the mutation because of a popular founding individual. However, often a few individuals have the same specific allele but do not have the mutation because of a previous recombination between the marker and the gene. This false association also can be caused by population dynamics in which some family lines always hold the same specific marker allele yet not associated with the mutated gene. A sensitivity, specificity, positive predictive value and a negative predictive value can be calculated from sufficient data for a genetic marker test. A currently available genetic linkage test for copper toxicosis is listed Table 230-3.

Genetic linkage tests generally are often temporary screening tests because, once a linked marker is documented, the genetic mutation is likely to be identified by positional cloning. An example of this is copper toxicosis in Bedlington terriers for which a linked marker and corresponding marker test were identified in 1997 (Yuzbasiyan-Gurkan et al., 1997). The genetic linkage test was verified in a larger population shortly thereafter (Rothuizen et al., 1999), and a number of years later the putative mutation was identified (van de Sluis et al., 2002).

Fig. 230-3 Gel electrophoresis results for a hypothetical genetic linkage test in a family. Marker A has three alleles that vary in size by two base pairs in size of a dinucleotide marker repeat such as CA. The marker is closely linked to the gene defect, with allele 1 usually being associated with the disease allele and alleles 2 and 3 usually being associated with the normal gene allele. The alleles from each individual can be separated and visualized on a gel by electrophoresis. Squares are males and circles are females. Individuals 1 and 8 are the parents and are both carriers. Individuals 4 and 5 are both affected and have two of the 1 alleles (only one band is visualized because the 1 alleles from each parent are the same size). The status indicated below each set of gel band for each individual is the most likely genetic status (Clear = likely clear, Carr = likely carrier, Aff = likely affected) for a hypothetical recessive disease. Genetic linkage tests are never 100% accurate because of recombination events and/or population dynamics, but they can be good screening tests if there is a low recombination frequency and a strong founder effect. Eventually the actual mutation should be able to be identified, and a direct gene test developed. Laboratories should always run positive and negative controls for all molecular genetic tests.

Table 230-3

Genetic Linkage Test for Canine Inherited Disorder

Disease	Breed(s)	Inheritance	Laboratory	Basis
Copper toxicosis	Bedlington Terrier	AR	Vetgen	PBL

AR, Autosomal-recessive; PBL, peer-reviewed publication. For complete laboratory details see Table 230-1. Genetic linkage tests are never 100% accurate and should be used as screening test only until the mutation is identified.

FUTURE TEST DEVELOPMENT, OTHER SERVICES, AND UPDATED TEST LISTS

The field of canine molecular genetics is evolving at a fast pace; therefore the list of available tests and services is also changing rapidly. Individual results for a direct mutation test generally have a straightforward interpretation. If direct mutation test results will be used in a breeding program or if results of a genetic linkage test are currently used, a canine geneticist should be consulted for genetic counseling. Many of the listed laboratories (see Table 230-1) and some other laboratories offer additional services such as individual DNA identification, parentage testing, DNA storage, coat color genetic testing, and/or karyotyping.

The principles and details outlined here apply equally well to testing for inherited disorders of cats. Updated lists of the available tests for dogs can be found at the website for the American Kennel Club Canine Health Foundation: http://www.akcchf.org/research/genetic_tests.pdf.

Treatment of Status Epilepticus

MICHAEL PODELL, *Northbrook, Illinois*

Status epilepticus (SE) is a life-threatening neurologic emergency characterized by prolonged seizure activity. SE has been defined as an epileptic seizure or sequence of recurrent seizures persisting for at least 30 minutes during which the patient does not regain normal consciousness (Drislane, 2005). A stricter criterion includes the presence of electrical seizure activity for at least 30 minutes' duration, even if consciousness is not impaired. However, data from human patients indicate that seizures lasting for at least 10 minutes are unlikely to stop on their own without pharmacologic intervention (DeLorenzo et al., 1999). Many epileptic dogs and cats exhibit recurrent generalized epileptic seizures within a 24-hour period, termed *cluster seizures*. Since little information is available on the electrical activity of the brain of these patients during these events, coupled with the fact that many of these cluster seizures are intermixed with difficult-to-observe partial seizures and abnormal behavior, it is possible that many of these affected animals are exhibiting a form of SE unique to this species. Failure to control these seizures can not only be a life-threatening event, but also may also contribute to poor long-term seizure control (Kwan, 2000).

INITIAL APPROACH AND DIAGNOSIS

The cause of SE is often related to whether previous epilepsy has been diagnosed. In general there has been no definitive evidence correlating SE to specific etiology. A higher proportion of dogs with previous seizures in the age range of 1 to 5 have idiopathic epilepsy. Approximately 25% of the SE cases in one study were idiopathic in nature (Bateman and Parent, 1999). Many of these animals develop SE or cluster seizures because of inadequate anti-epileptic drug (AED) therapy, drug tolerance, or recent changes in therapy (Saito et al., 2001). In contrast, dogs with new onset of seizure activity that are younger than 1 year or older than 7 years are more likely to have symptomatic epilepsy as a result of a predisposing underlying brain disease. Younger animals are more susceptible to toxicity, metabolic encephalopathies (e.g., portosystemic shunts), and encephalitic diseases as a cause for seizures. However, older cats and dogs are more likely to suffer from underlying brain neoplasm, cerebrovascular disease, and metabolic encephalopathy from advancing renal or liver disease.

Immediate diagnostic testing should revolve around the current physiologic status of the seizing animal. Basic cardiopulmonary resuscitation requirements of ensuring that there is an open airway with adequate blood oxygenation with a pulse oximeter and/or blood gas and providing

fluid support to maintain normal blood pressure is critical. Minimal STAT testing includes analysis of blood glucose, electrolytes (sodium, potassium, calcium, chloride), and packed cell volume and total plasma protein. Optimal STAT testing includes a complete blood count, serum chemistry panel (to include creatine phosphokinase), blood gas analysis, and existing AED serum concentrations. However, the latter tests typically are unavailable to most emergency clinics. Serum should be collected in a nonserum separator tube at the time of admission for future submission of AED serum concentrations.

Delayed or advanced diagnostic testing entails determination of the underlying cause for the seizures, as well as evaluation of existing serum AED levels as applicable. These tests include thoracic and abdominal radiographs, possible abdominal ultrasound, and any follow-up biochemical testing as indicated by the initial laboratory testing. Advanced imaging of the brain (i.e., magnetic resonance imaging scan) is strongly recommended for any new-onset seizure dog over the age of 7 years and for any cat proven not to have a metabolic disease. Collection of cerebrospinal fluid typically depends on results of the imaging. Results of neuroimaging can be abnormal as a consequence of SE in a high proportion of dogs (Platt and Haag, 2002).

TREATMENT

The goals of treating SE are simple: *stop* the seizures, *protect* the brain from further damage, and allow full *recovery* from the episode of SE. The longer an animal seizes, the greater the chances are that neuronal injury will occur. Brain damage in the epileptic patient begins at the subcellular level, progresses to the cellular level, and over time will result in overt pathologic changes to the brain that may lead to permanent changes in brain function. With the onset of a seizure, several mechanisms occurring simultaneously can lead to neuronal death. Understanding the effect of these changes on the brain is important when planning proper emergency seizure therapy. Several factors lead to direct cytotoxicity, including hypoxemia, ischemia, and excitotoxicity. Excitotoxicity is caused by an excessive activation of glutamate receptors, an excitatory neurotransmitter, resulting in an excessive and prolonged influx of intracellular calcium that disrupts the normal metabolic activity of the cell. Thus the acute pathogenesis of brain injury during seizures dictates therapy designed to stop the ictal event, reduce intracranial pressure by decreasing cerebral edema, and provide the care to support neuronal metabolic activity. Cerebral edema and hippocampal necrosis have been identified in

cats with prolonged seizure activity, suggesting that rapid-onset cytotoxicity may occur as compared to dogs (Fatzner et al., 2000).

Management of SE is most effective when a preestablished protocol is followed. Although individual variations in treatment protocols exist in both human and veterinary medicine, the key to a successful outcome is threefold: (1) Establish physiologic supportive care; (2) provide effective and immediate-acting AED therapy; and

(3) institute AED therapy that will maintain prolonged antiepileptic action (Podell, 1996). Specific AED therapy revolves around the ability of the drug to rapidly enter the brain, provide effective and immediate seizure cessation, possess no-to-minimal adverse systemic or neurologic effects, and be retained in the brain to prevent future seizures. The protocols listed in Fig. 231-1 provide a sequential plan of action starting from initial care through complete anesthesia for the dog and cat.

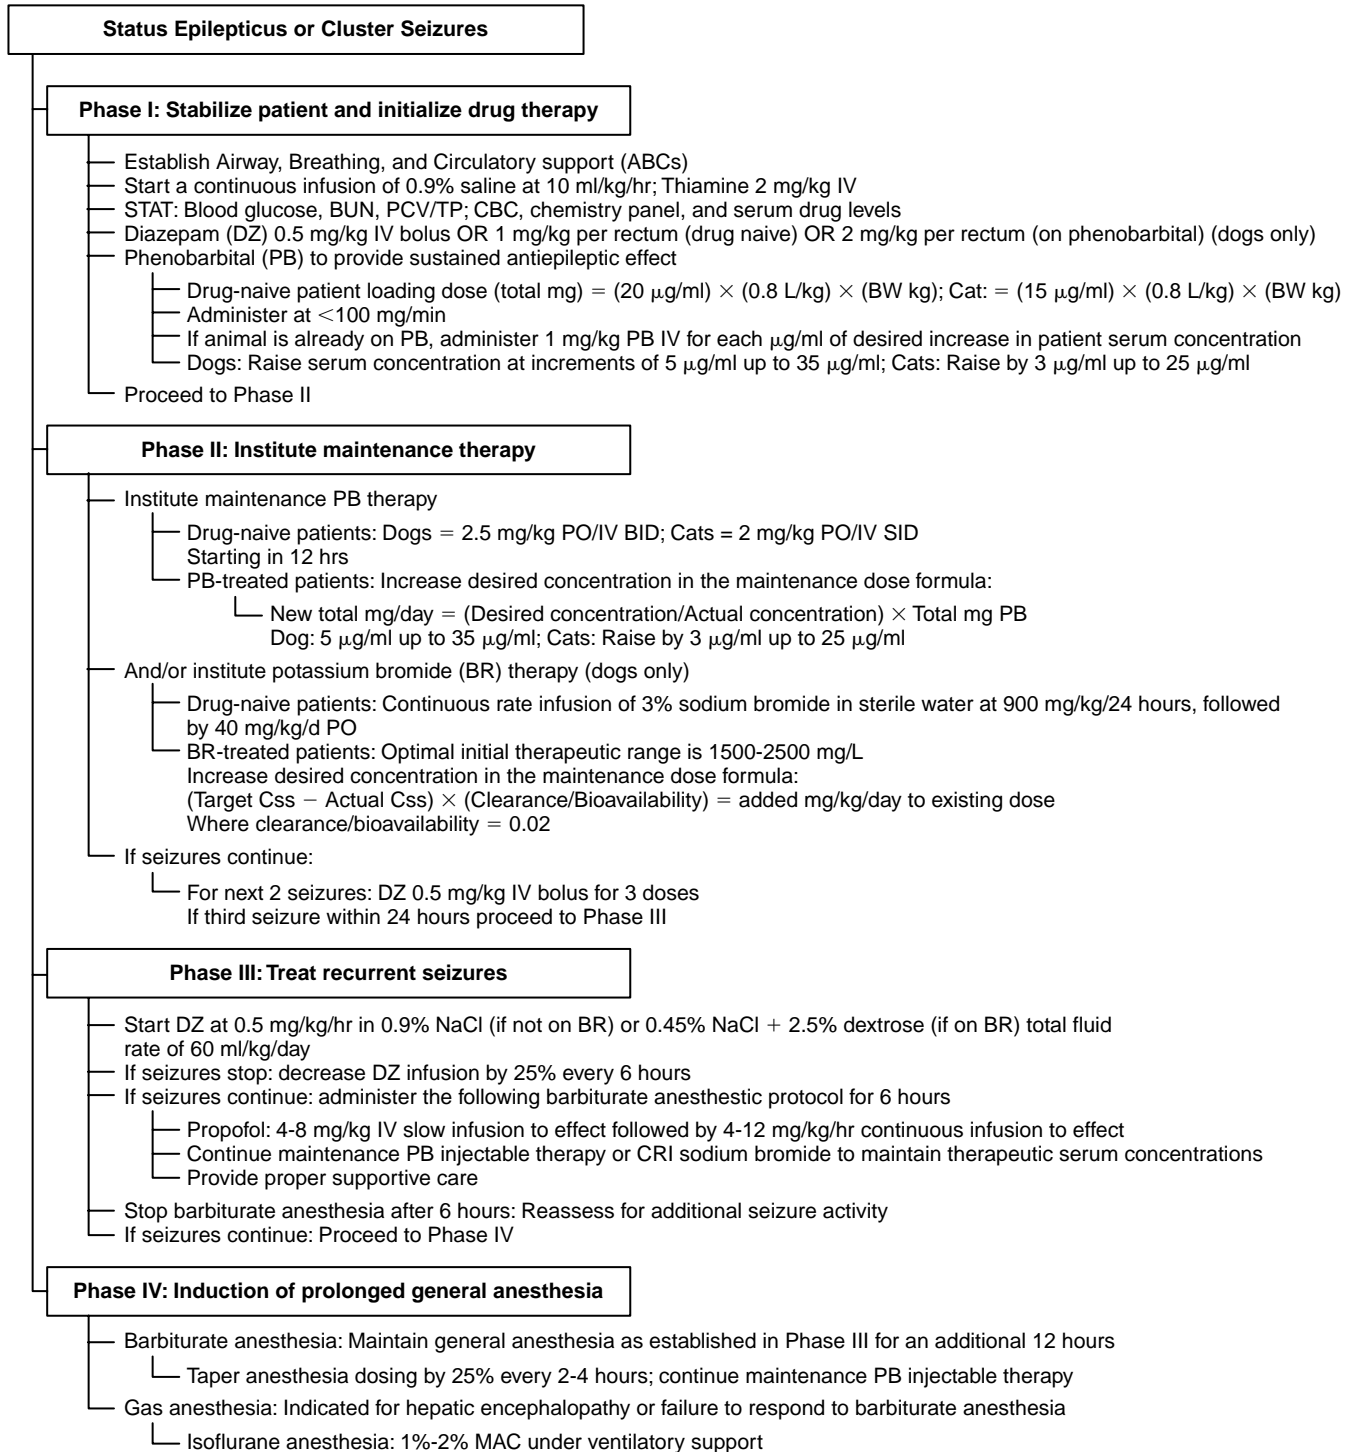

Fig. 231-1 Medical management of status epilepticus in the dog and cat.

The majority of animals that present for SE have experienced or are actively suffering from generalized seizure activity. Immediate cessation of seizure activity is the primary treatment goal (see Fig. ##-1). Administration of benzodiazepine therapy is the most effective method to rapidly stop electrical epileptic seizure activity. Administration of diazepam per rectum at 1 mg/kg in drug-naïve dogs or 2 mg/kg in dogs on phenobarbital (PB) provides a rapid method of initiation of drug therapy that is especially helpful before intravenous catheter placement and diazepam intravenous therapy (0.5 mg/kg intravenously [IV]). The benefit of rectal administration in cats has not been well documented. Higher doses of diazepam are not recommended because the risk of respiratory depression outweighs any further anticonvulsant benefit. Midazolam (0.3 mg/kg IV) and lorazepam (0.2 mg/kg IV) are alternative benzodiazepine therapies with proven prolonged anticonvulsant benefit in people but are more expensive and unproven in canine or feline SE.

All cases of SE are treated as “trauma” patients. It is essential to maintain a patent airway, support proper breathing patterns and oxygenation, and provide circulatory support. Stabilizing the patient and reversing the physiologic sequelae of prolonged or recurrent seizure activity within the first 30 minutes of SE are critical since dogs develop arterial hypertension, increased cerebral blood flow, hypoxemia, hypercarbia, hyperglycemia, and lactic acidosis. Subsequent changes may include arterial hypotension, decrease in blood pH, pyrexia, hyperkalemia, myoglobinuria, and hypoglycemia. The combination of circulatory collapse, organ hypoperfusion, and energy depletion can lead to severe, irreversible organ failure (renal, cardiac, hepatic). Thiamine (2 mg/kg IV) should be administered since this B vitamin is an important cofactor for cerebral aerobic glycolytic metabolism. Dextrose-containing solutions should *not* be administered unless hypoglycemia is documented. Hyperglycemia in the face of reduced oxidative phosphorylation in the brain results in central nervous system lactic acidosis and resultant neuronal necrosis. Mannitol at 1 g/kg IV over a 15-minute period along with low-steroid therapy (dexamethasone SP 0.25 mg/kg IV) is recommended to treat for cerebral edema.

Following initial diazepam therapy, institution of a maintenance therapy is critical to prevent seizure recurrence. PB therapy is the current drug of choice because of its ability to provide a rapid intravenous loading dose, its efficacy to suppress seizure activity, a long elimination half-life, and cost effectiveness. An initial PB dose of 16 mg/kg and 12 mg/kg IV given at a rate of 100 mg/minute will provide a serum concentration of 20 mcg/ml and 15 mcg/ml in drug-naïve dogs and cats, respectively. For previously treated dogs the goal is to raise the PB serum concentration by 5 mcg/ml by using either STAT laboratory testing or the most recent PB serum concentration, to a maximum of 35 mcg/ml. PB has a more prolonged elimination half-life in the cat; therefore sedative effects may be prevalent (Parent and Quesnel, 1996). Thus the initial therapeutic range is lower, typically between 10 and 20 mcg/ml, and dosing is highly individualized. Most cats can be treated with a maintenance dosage of 1 to 2 mg/kg/day, with once daily dosing initially at night.

The author recommends bromide (BR) loading therapy in dogs with suspected or documented hepatic disease or cases refractory to PB therapy. I prefer intravenous loading of sodium BR over oral or rectal loading techniques because this protocol provides a more predictable rise in bromide serum concentration without the risk for adverse gastrointestinal problems. A 3% sterile sodium BR solution is prepared by diluting 30 g of gas-sterilized sodium BR salt into 1 L of sterile water and administered through a 40- μ m filter at a dose of 900 mg/kg/24 hours to achieve a serum BR concentration of 2000 mg/L at the end of the loading period. Potassium BR is then dosed at 40 mg/kg PO every 24 hours. There is a potential for enhanced sedation with this treatment that typically resolves within several days. BR therapy in cats is *not* recommended as a standard therapy because of the relatively high prevalence of adverse respiratory problems (Boothe, 2002). Cats can develop cough and more severe respiratory signs suggestive of an allergic asthmatic disease.

Levetiracetam (Keppra) is the S-enantiomer of the ethyl analogue of piracetam that binds to SV2A, a synaptic vesicle protein, which correlates to anticonvulsant potency. The drug is well absorbed without hepatic metabolism, has minimal protein binding, is available as a parenteral formulation, and has minimal adverse effects. An initial loading dose of 60 mg/kg IV over 30 minutes is recommended, followed by an oral maintenance dose of 20 mg/kg every 8 to 12 hours, as levetiracetam has a relatively short elimination half-life of 4 to 8 hours in dogs. No pharmacokinetic data could be found for cats. Although levetiracetam is considerably more expensive than bromide therapy, I have found it to be an effective alternative to bromide loading without the potential for posttreatment sedation.

Recurrent seizure activity beyond this initial therapy is treated with continuous rate infusion (CRI) of diazepam (see Fig. 231-1). A gradual taper of 25% every 6 hours is recommended to avoid potential withdrawal-induced seizure activity. Longer-term barbiturate CRI is the next level of treatment for breakthrough seizure activity. Propofol is recommended because of the short-elimination half-life and subsequent ability for rapid awakening. The initial induction dose is 4 to 8 mg/kg IV to effect followed by a CRI of 8 to 12 mg/kg/hour. Higher doses of propofol are typically needed to achieve optimal treatment with burst suppression and absence of epileptic activity on electroencephalogram monitoring in people and dogs. Barbiturate CRI treatment is recommended for an initial 6-hour period before cessation. Induction of prolonged general anesthesia with CRI barbiturate is instituted for 24 hours if breakthrough seizures occur. Isoflurane general anesthesia is the last treatment phase and typically is reserved for patients with recurrent seizure activity or dogs with hepatic disease.

MONITORING AND SUPPORTIVE CARE

Generalized convulsive SE is a dynamic condition, with a progressive diminution of convulsive activity as the seizures continue. Thus observation alone may be an inadequate method of determining seizure control. Monitoring of electroencephalographic activity has been instituted to ensure that complete cessation of all electrical epileptic activity has been achieved. Improvements in seizure

control and eventual outcome can be related to the ability to determine cessation of all epileptic brain activity. Other parameters to monitor include heart rate, blood pressure, respiratory rate, pulse oximetry, and serial neurologic examinations. Rectal temperature should be closely monitored during the first hour. Animals should be cooled with ice and cold water if rectal temperature is 104°F or higher. Cooling should stop when rectal temperature is 102°F to prevent rebound hypothermia. Endotracheal intubation and assisted ventilation may be required in patients on barbiturate CRI with induced general anesthesia.

In conclusion, SE is a serious, life-threatening disorder that requires rapid medical intervention. Recurrence of seizure activity is often the result of failure to maintain continuous therapeutic serum AED levels for sufficient periods of time to suppress epileptic activity. Successful treatment requires early recognition and intervention and the use of a standardized treatment protocol. A preemptive treatment protocol as presented here allows patients to benefit not only from the initial relief from current seizure activity but also from potential overall improvement in long-term seizure control.

New Maintenance Anticonvulsant Therapies for Dogs and Cats

CURTIS W. DEWEY, *Ithaca, New York*

Over the last 15 years the paradigm for treating dogs and cats with seizure disorders has changed, coincident with the introduction of several new anticonvulsant drugs. Although phenobarbital (dogs and cats) and bromide (dogs) remain valuable first-choice anticonvulsant drug choices for pets with seizure disorders, a number of alternative drugs can be used as either adjunctive (i.e., for refractory seizures) or sole therapeutic options. The major impediments to widespread use of these newer anticonvulsant drugs are principally increased cost compared with phenobarbital and bromide and clinical unfamiliarity with their usage. Since several of these drugs (gabapentin, zonisamide, levetiracetam) are now available in generic forms, cost is now less of a concern. Information is available concerning several newer anticonvulsant drugs for canine use. Unfortunately much of the information regarding new anticonvulsant therapy for cats remains largely anecdotal. Despite this limitation, there is sound clinical evidence supporting the use of levetiracetam in cats as an add-on drug for patients that are refractory to phenobarbital therapy. This chapter summarizes some of these newer anticonvulsant drugs with recommendations based on published literature and my own clinical experience. Additionally, the next generation of some of these compounds is discussed briefly.

GABAPENTIN

Gabapentin, a structural analog of γ -aminobutyric acid (GABA), probably exerts its antiseizure effects via inhibition of voltage-gated calcium channels in the brain. Gabapentin is well absorbed in both dogs and people, with peak serum concentrations occurring within 1 to 3 hours after ingestion. In dogs 30% to 40% of the orally administered dose of gabapentin undergoes hepatic metabolism to N-methyl-gabapentin. Despite undergoing some hepatic metabolism in dogs, there is no appreciable induction of hepatic microsomal enzymes in this species. The half-life of elimination for gabapentin in dogs is between 3 and 4 hours. Because of its short half-life in dogs, gabapentin probably needs to be administered at least every 8 hours and possibly every 6 hours to maintain serum gabapentin concentrations within the therapeutic range. The potential need for every-6-hour dosing can make it difficult for some pet owners to administer gabapentin consistently.

The recommended *daily* dosage range of gabapentin for dogs is 25 to 60 mg/kg of body weight, *divided*, every 6 to 8 hours. I recommend an initial dose regimen of 10 mg/kg of body weight every 8 hours. The suspected therapeutic plasma concentration for dogs is 4 to 16 mg/L. Gabapentin concentrations are seldom measured in dogs.

Efficacy of gabapentin in dogs has been evaluated in some small studies. In one prospective study evaluating gabapentin as an add-on therapy for dogs with refractory seizure activity, there was no significant decrease in overall seizure activity over a 4-month evaluation period. Despite this, 3 of 17 dogs became seizure free, and 4 others experienced a 50% or more reduction in seizure frequency during the evaluation period. In a similar study evaluating 11 dogs, an overall significant reduction in seizure frequency was found, and 6 dogs experienced a 50% or more reduction in seizure frequency. Sedation and pelvic limb ataxia were the only reported side effects in these two studies. In my experience gabapentin is occasionally helpful as an anticonvulsant drug in dogs. In humans gabapentin appears to be much more effective in the treatment of focal seizure disorders than in that of generalized seizures.

Long-term canine toxicity trials for gabapentin have not been reported. However, the drug seems to be very well tolerated in this species, usually with little to no side effects. Sedation does not appear to be a major problem. However, I have had many clients report that their dogs experienced mild sedation or mild polyphagia and weight gain associated with gabapentin use.

Only anecdotal information is available regarding gabapentin use in cats. An oral dose of 5 to 10 mg/kg of body weight every 8 to 12 hours has been suggested but is not based on any published data. To my knowledge there is no information regarding either the safety or efficacy of chronic gabapentin administration to cats.

A new gabapentin analog, pregabalin, has recently been approved for human use. Pregabalin has an increased affinity for the $\alpha 2\delta$ -subunit of voltage-gated calcium channels compared with gabapentin and is purportedly more effective in people than its predecessor as both an anticonvulsant and a pain-relieving drug. My colleagues and I have recently investigated the pharmacokinetics of pregabalin in normal dogs. In addition, we have preliminary data regarding the efficacy of pregabalin in dogs with refractory epilepsy. Pregabalin has a favorable pharmacokinetic

profile in dogs and appears to be an effective add-on anticonvulsant drug, based on a limited number of cases.

FELBAMATE

Felbamate is a dicarbamate drug that has demonstrated efficacy for both focal (partial) and generalized seizures in experimental animal studies and human clinical trials. Proposed mechanisms of action include blocking of N-methyl-D-aspartate (NMDA)-mediated neuronal excitation, potentiation of GABA-mediated neuronal inhibition, and inhibition of voltage-sensitive neuronal sodium and calcium channels. Felbamate may also offer some protection to neurons from hypoxic/ischemic damage.

Approximately 70% of the orally administered dose of felbamate in dogs is excreted in the urine unchanged; the remainder undergoes hepatic metabolism. The half-life of felbamate in adult dogs is typically between 5 and 6 hours (range 4 to 8 hours). Felbamate is well absorbed after oral administration in adult dogs, but bioavailability in puppies may be only 30% that of adults. The half-life of elimination in puppies has also been shown to be much shorter than in adult dogs (approximately 2.5 hours). For adult dogs I recommend an initial felbamate dosage regimen of 15 mg/kg of body weight every 8 hours. Felbamate has a wide margin of safety in dogs, with serious toxic effects usually not apparent below a daily dose of 300 mg per kilogram of body weight per day. If the initial dose of felbamate is ineffective, the dose is increased by 15-mg/kg increments every 2 weeks until efficacy is achieved, unacceptable side effects are evident, or the drug becomes cost prohibitive. The therapeutic range for serum felbamate concentration in dogs is believed to be similar to that in people (20 to 100 mcg/ml). Typically serum felbamate assays are costly. In addition, the wide therapeutic range and low toxicity potential of felbamate make routine serum drug monitoring of questionable clinical value. I do not routinely check felbamate levels in dogs.

The limited published material regarding clinical efficacy of felbamate is similar to my experience. In one report of refractory epileptic dogs, 12 of 16 patients experienced a reduction of seizure frequency following initiation of felbamate therapy. In another report of six dogs with suspected focal seizure activity, all dogs experienced a substantial reduction in seizure frequency when felbamate was used as a sole anticonvulsant drug; two of these dogs became seizure free.

I have used felbamate extensively in the treatment of dogs with seizure disorders. Felbamate appears to be very effective both as an add-on therapy and as a sole anticonvulsant agent for patients with focal and generalized seizures. Because of its lack of sedation, felbamate is particularly useful as monotherapy in dogs exhibiting obtunded mental status as a result of their underlying neurologic disease (e.g., brain tumor, cerebral infarct). I have found side effects from felbamate to be very infrequent, especially when it is used as a sole anticonvulsant drug. Hepatic dysfunction associated with felbamate use tends to resolve following discontinuation of the drug. In dogs with evidence of preexisting hepatic disease, felbamate should be avoided. Because of the potential for hepatotoxicity, it is recommended that serum biochemistry analysis be performed every 6 months for dogs

receiving felbamate, especially if given concurrently with phenobarbital. It may also be advisable to evaluate complete blood counts every few months in the unlikely event that a blood dyscrasia develops.

Side effects are infrequently observed with felbamate use in dogs. Unlike other anticonvulsants, felbamate does not cause sedation. Because felbamate does undergo some hepatic metabolism, liver dysfunction is a potential side effect. In one study 4 of 12 dogs receiving felbamate as an add-on therapy developed liver disease; however, each of these dogs was also receiving high doses of phenobarbital. In humans felbamate has been shown to increase serum phenobarbital concentrations in some patients receiving combination therapy. It is unclear whether felbamate, phenobarbital, or the combination of the two drugs is responsible for the reported hepatotoxicity in dogs. In humans serious hepatotoxicity is rarely associated with felbamate use and usually occurs in patients concurrently receiving other anticonvulsant drugs. Aplastic anemia (caused by bone marrow suppression) has been reported to occur in people receiving felbamate at a rate of 10/100,000 patients; this uncommon and severe side effect is also usually encountered with patients receiving combination anticonvulsant drug therapy. Fortunately this does not appear to occur in dogs. However, in one report, reversible bone marrow suppression was suspected in two dogs receiving felbamate; one dog developed mild thrombocytopenia, the other mild leukopenia. Both of these abnormalities resolved following discontinuation of the drug. One patient in this report developed bilateral keratoconjunctivitis sicca (KCS); it is unknown whether this was related to felbamate use, though I have encountered several patients on felbamate that developed KCS. Generalized tremor activity in small-breed dogs receiving high doses of felbamate has also been reported as a rarely encountered side effect.

To my knowledge there is no clinical information regarding the use of felbamate in cats. Because of the potential for felbamate-associated hepatotoxicity and blood dyscrasias in dogs, felbamate is not likely to become a viable anticonvulsant option for cats.

Because of the problems of hepatotoxicity and blood dyscrasias occasionally associated with felbamate use in people, a new derivative of the drug—fluorofelbamate—has been developed and is undergoing clinical trials for human use. In experimental animal epilepsy models fluorofelbamate has been shown to have equal or superior anticonvulsant potency in comparison with felbamate. A reactive aldehyde intermediate that is formed from felbamate metabolism has been linked to the hepatic and hematologic side effects of this drug. This toxic intermediate is not produced from metabolism of fluorofelbamate.

LEVETIRACETAM

Levetiracetam is a new piracetam anticonvulsant drug that has demonstrated efficacy in the treatment of focal and generalized seizure disorders in people, as well as in several experimental animal models. Although generally recommended as an add-on anticonvulsant drug, levetiracetam has been used successfully as monotherapy in people. In humans with refractory epilepsy, levetiracetam has manifested antiseizure effects within the first

day of treatment. The mechanism of action for the anticonvulsant effects of levetiracetam is not entirely clear, but appears to be related to its binding with a specific synaptic vesicle protein (SV2A) in the brain. Unlike other anticonvulsant drugs, levetiracetam does not appear to directly affect common neurotransmitter pathways (e.g., GABA, NMDA) or ion channels (e.g., sodium, T-type calcium). Levetiracetam has demonstrated neuroprotective properties and may ameliorate seizure-induced brain damage. Levetiracetam has also been reported to have an “anti-kindling” effect, which may diminish the likelihood of increasing seizure frequency over time. Orally administered levetiracetam is approximately 100% bioavailable in dogs, with a serum half-life of 3 to 4 hours. Levetiracetam appears to exert an anticonvulsive effect that persists longer than its presence in the bloodstream would suggest. In dogs approximately 70% to 90% of the administered dose of levetiracetam is excreted unchanged in the urine; the remainder is hydrolyzed in the serum and other organs. There does not appear to be any appreciable hepatic metabolism of levetiracetam in either humans or dogs. The effective serum levetiracetam concentration in people is 5 to 45 mcg/ml. Because there is no clear relationship between serum drug concentration and efficacy for levetiracetam and since the drug has an extremely high margin of safety, routine therapeutic drug monitoring is not typically recommended for this drug in humans.

I have used levetiracetam in dogs as an add-on therapy with favorable results. In a recent report use of levetiracetam as an add-on drug in epileptic dogs was associated with a significant reduction (54%) in seizure frequency, with no apparent side effects. Because of its paucity of side effects and lack of hepatic metabolism, levetiracetam also presents an attractive anticonvulsant choice for patients with hepatic dysfunction. It has recently been suggested that some dogs that initially improve with levetiracetam therapy may return to baseline seizure frequency over a 4- to 8-month period (the “honeymoon effect”).

I recommend an initial dosing schedule of 20 mg/kg of body weight every 8 hours based on both pharmacokinetic data and clinical experience. This dose can be increased by 20-mg/kg increments until efficacy is achieved, side effects become apparent, or the drug becomes cost prohibitive. At present, I recommend therapeutic blood monitoring of levetiracetam in dogs and cats, both for purposes of establishing a therapeutic range of the drug for these species, and for individual therapeutic decision making.

Long-term toxicity data for levetiracetam in dogs confirm that the drug is extremely safe. In one study dogs were administered oral levetiracetam at doses up to 1200 mg/kg/day for 1 year. One of eight dogs receiving 300 mg/kg/day developed a stiff/unsteady gait. Other side effects (salivation, vomiting) were confined to dogs receiving 1200 mg/kg/day. There were no treatment-related mortalities or histopathologic abnormalities.

My colleagues I and have prospectively investigated the use of oral levetiracetam as an add-on anticonvulsant therapy for epileptic cats refractory to phenobarbital. Levetiracetam appears to be very well tolerated in this species, usually with no apparent side effects. The half-life of elimination is approximately 3 hours after oral administration. A dose of 20 mg/kg PO every

8 hours typically achieves a serum drug level within the therapeutic range reported for people. Two of 12 cats experienced transient inappetance and lethargy that resolved without dose adjustment within 2 weeks. Although there is some degree of variability among cats, the mean reduction of seizure frequency in cats receiving levetiracetam as an add-on drug is approximately 68%; this was found to be statistically significant when compared to the prelevetiracetam time period. In addition, 7 of 10 cats evaluated for seizure frequency reduction were responders (i.e., reduction of seizure frequency of 50% or more), with a mean reduction of seizures of 92%. I consider levetiracetam to be the preferred add-on anticonvulsant drug for cats receiving phenobarbital because of lack of serious side effects and evidence of efficacy.

Intravenous levetiracetam has shown promise as a treatment for experimental status epilepticus in a rat model. In this study intravenous levetiracetam and diazepam appeared to potentiate the anticonvulsant effect of one another. Intravenous levetiracetam seems well tolerated in dogs, even at doses as high as 400 mg/kg of body weight. I have had limited but positive clinical experience using intravenous levetiracetam in dogs. Currently the pharmacokinetics of intravenous levetiracetam in normal dogs is under investigation.

Since the discovery of levetiracetam's unique binding site in the brain, two related anticonvulsant drugs—brivaracetam and seletracetam—with higher affinity than levetiracetam for the SV2A receptor have been developed. These drugs have been demonstrated to have improved anticonvulsant activity over levetiracetam in experimental animal seizure models and currently are being evaluated in human clinical epilepsy trials.

ZONISAMIDE

Zonisamide is a sulfonamide-based anticonvulsant drug recently approved for human use; it has demonstrated efficacy in the treatment of both focal and generalized seizures in people with minimal side effects. Suspected anticonvulsant mechanisms of action include blockage of T-type calcium and voltage-gated sodium channels in the brain, facilitation of dopaminergic and serotonergic neurotransmission in the central nervous system, scavenging free radical species, enhancing actions of GABA in the brain, inhibition of glutamate-mediated neuronal excitation in the brain, and inhibition of carbonic anhydrase activity. Zonisamide is metabolized primarily by hepatic microsomal enzymes, and the half-life in dogs is approximately 15 hours. In humans it has been shown that the elimination half-life of zonisamide is dramatically shorter in patients already receiving drugs that stimulate hepatic microsomal enzymes than in patients who are not receiving such drugs. A similar phenomenon appears to occur in dogs. When used as an add-on therapy for dogs already receiving drugs requiring hepatic metabolism (e.g., phenobarbital), I recommend an initial oral zonisamide dosage schedule of 10 mg/kg of body weight every 12 hours. This dosage regimen has been shown to maintain canine serum zonisamide concentrations within the therapeutic range reported for people (10 to 40 mcg/ml) when used

as an add-on therapy. For dogs not concurrently receiving drugs that induce hepatic microsomal enzymes, it is recommended to start zonisamide at a dosage of 5 mg/kg of body weight every 12 hours. I generally check trough serum zonisamide concentrations after approximately 1 week of zonisamide treatment. Zonisamide has a high margin of safety in dogs. In one study minimal side effects occurred in beagles administered daily zonisamide doses up to 75 mg/kg of body weight per day for 1 year.

In one study zonisamide was found to decrease seizure frequency by at least 50% in 7 of 12 dogs with refractory idiopathic epilepsy. In this responder group the mean reduction in seizure frequency was 81.3%. In six of the seven responder dogs phenobarbital was able to be reduced by an average of 92.2%. Mild side effects (e.g., transient sedation, ataxia, vomiting) occurred in six dogs (50%); none of the side effects was considered severe enough to discontinue zonisamide therapy. In a more recent, similarly designed study, 9 of 11 refractory epileptic dogs treated with zonisamide were responders, with a median seizure reduction of 92.9%; transient ataxia and sedation occurred in six dogs.

Zonisamide has been shown to be very effective as a sole anticonvulsant drug in people. I have used zonisamide as a sole anticonvulsant drug in a large number of dogs. These have been primarily small-breed patients whose owners wished to avoid side effects associated with phenobarbital and bromide use. Zonisamide appears to be effective as a sole anticonvulsant therapy, with few- to-no apparent side effects in dogs.

I have treated two epileptic cats with zonisamide as an add-on to phenobarbital therapy. One cat became anorexic, necessitating drug discontinuation. The other cat experienced a substantial reduction in seizure frequency. This cat also had no side effects or blood work abnormalities attributable to zonisamide therapy after approximately 1 year of administration. Further data are

needed regarding the use of zonisamide in cats before it can be recommended for use in this species.

Treatment of Primary Central Nervous System Inflammation (Encephalitis and Meningitis)

ANDREA TIPOLD, *Hannover, Germany*

TREATMENT OF CENTRAL NERVOUS SYSTEM INFLAMMATION

Central nervous system (CNS) inflammatory lesions are an important group of disorders in all animal species and a challenge for the veterinarian. In our referral clinic this group of diseases accounts for about 10% of all neurologic cases in small animals. Besides causing severe neurologic impairment, several of these diseases are zoonoses. There are a large number of disorders in this category of inflammatory disease of both known and idiopathic etiology. Examples of meningoencephalomyelitides of known cause include canine distemper encephalitis, feline infectious peritonitis (FIP), central European tick-borne encephalitis, rabies, pseudorabies, canine herpesvirus encephalitis, West Nile virus infection, encephalomalacia caused by canine parvovirus, encephalitis caused by canine parainfluenza virus, and postvaccinal encephalitis after distemper or rabies vaccination. Besides viral infections, protozoal encephalomyelitis, bacterial meningoencephalitis, and mycotic infections of the CNS are causes of neurologic signs. In addition, a variety of meningoencephalomyelitides of unknown etiology are encountered. These include diseases with suspected viral etiology such as periventricular encephalitis; granulomatous meningoencephalomyelitis (GME); steroid-responsive meningitis-arteritis (SRMA); necrotizing meningoencephalitis of pugs, Maltese, and Yorkshire terriers; eosinophilic meningoencephalomyelitis; and a variety of inflammatory conditions of unknown origin, which are not even classified by histopathology. Because of this wide range of inflammatory conditions, it is not surprising that distinguishing the cause of meningoencephalomyelitides remains a diagnostic and therapeutic challenge for the clinician, even with newly developed techniques such as magnetic resonance imaging (MRI) and polymerase chain reactions (PCRs).

Before a treatment plan can be established, the diagnostic workup of such lesions has to be performed. Inflammatory lesions are not associated with classical clinical signs. Depending on which part of the CNS is affected, the clinical signs may vary from spinal cord to intracranial signs; in some cases the nerve roots and muscles are also involved. Some diseases have a different clinical picture, depending on the age of the patient. In this chapter the workup of CNS inflammation is discussed briefly, followed by the appropriate treatment, depending on the etiology of the disease.

CLINICAL SIGNS

The presence of multifocal signs, often considered the hallmark clinical feature of this group of diseases, is only noticed in about one-third of affected dogs. Other cases are presented with signs suggestive of a focal lesion in a region of the brain or the spinal cord. Signalment, history, and extraneural signs contribute, to a limited degree, to establishing a specific diagnosis. In breed-specific encephalitides the signalment can give a certain hint (pugs and Maltese, Yorkshire terriers, greyhounds, Chihuahua, Shih Tzu). The presence of extraneural signs in dogs with focal lesions may be helpful in establishing a presumptive diagnosis of meningoencephalomyelitis. A typical extraneural sign, which is found only in dogs with distemper—in about 20% of cases—is hyperkeratosis of the foot pad or the nose. Dogs with distemper may also develop rapid cachexia. An elevated body temperature may be seen in dogs with different encephalitides, mostly after bacterial infection, and in dogs with SRMA.

In many cases the localization of the lesion is of little help in establishing a diagnosis since a large variety of neurologic signs are associated with different inflammatory diseases. Certain signs occur more often with certain diseases (e.g., myoclonus, involuntary rhythmic jerking of single muscles or muscle groups, has been considered to be nearly pathognomonic for distemper). However, myoclonus may also occur in non-distemper meningoencephalomyelitis (albeit less frequently). In the acute form of SRMA typical clinical symptoms are cervical rigidity and neck pain. In pug encephalitis the most consistent sign is the occurrence of focal or generalized seizures. In Yorkshire terriers signs of encephalitis are referable to brainstem injury (abnormal mental status, multiple cranial nerve deficits, and gait abnormalities). Hydrocephalus with periventricular encephalitis occurs in puppies between 2 and 6 months of age. These puppies develop acute neurologic signs with a rapid skull enlargement. Neurologic signs include forebrain signs such as behavioral changes and central blindness.

CLINICAL PATHOLOGY

Clinical pathology tests, especially analysis of cerebrospinal fluid (CSF), provide the principal information needed for diagnosis of inflammatory CNS diseases. The CSF cell count, cytology, and demonstration of a high immunoglobulin-G (IgG) index are pivotal to establishing the

diagnosis of inflammatory disease. The IgG index helps to identify intrathecal IgG-production calculating IgG and albumin in CSF and serum. In addition, CSF examination may help to differentiate some diseases. For example, a high IgA concentration in serum and CSF is common in dogs with SRMA. Pleocytosis with predominantly lymphocytes and plasma cells is found in viral infections and during the chronic phase of SRMA, in GME, and in breed-specific necrotizing encephalitis. A predominantly neutrophilic pleocytosis is characteristic of bacterial infections and the acute stage of SRMA. A mixed cell population is frequently seen in protozoal diseases, FIP, chronic bacterial infections, necrotic lesions, and GME. Eosinophils are found in the rare eosinophilic encephalitis of unknown origin; in protozoal, parasitic, and mycotic infections; and also occasionally in GME and FIP.

OTHER SPECIAL EXAMINATIONS

Ancillary diagnostic tests contribute to the diagnoses of meningoencephalomyelitides to varying degrees. Electroencephalography is helpful for detecting an ongoing irritating process, and electromyography can help identify lower motor neuron lesions.

Imaging techniques are useful for excluding diseases other than inflammation or for finding extraneural primary lesions such as in bacterial encephalitis, which is usually the result of hematogenous dissemination of bacteria or spreading of an inflammation in the cranium (e.g., otitis media/interna or sinusitis) or the vertebral column (e.g., diskospondylitis, biting wounds). In addition, imaging may uncover secondary CNS changes such as hydrocephalus secondary to an inflammatory process related to CSF flow obstruction or defective absorption. When computed tomography (CT) demonstrates contrast enhancement of multifocal lesions, the suspicion of an inflammatory disease is raised. MRI provides the advantage of better visualization of soft-tissue (brain and spinal cord). This facilitates the discovery of inflammatory CNS lesions per se. Inflammatory CNS disease is suggested by the presence of multifocal, hyperintense lesions in T2-weighted images, which appear more or less hypointense in T1-weighted images and are enhanced by contrast. However, even with MRI techniques, different encephalitides cannot be distinguished with certainty, and some neoplasms create the same appearance. In addition, single granulomas may mimic a neoplastic lesion. MRI has also revealed hyperintensity in T2-weighted images and contrast enhancement in areas of myelin swelling and demyelination in acute canine distemper virus infection without the presence of inflammatory lesions.

Thus biopsy sampling is highly recommended to obtain an exact diagnosis, especially in inflammatory lesions of unknown origin. Refinement of future therapies of brainstem inflammation will require definitive diagnosis including results of a biopsy sample. In the clinical workup without histopathologic examination, a diagnosis of a specific inflammatory/infectious disease must be based mainly on a combination of clinical, laboratory, imaging, and CSF findings.

Bacterial Infection

Many dogs with bacterial encephalitis can be diagnosed with high probability on the basis of severe CSF changes

with neutrophilic pleocytosis and rapid deterioration. With the aid of imaging techniques, extraneural lesions such as sinusitis or otitis media may be detected as predisposing causes. Microbiologic examinations of the CSF (culture, PCR) might identify a specific agent, but this is uncommonly found. A rapid diagnostic workup is necessary to start treatment before the CNS tissue is destroyed irreparably.

Viral Encephalitis

A sizable proportion of dogs with distemper can be diagnosed based on a combination of their young age, hyperkeratosis, lymphopenia, myoclonus, normal or moderately abnormal CSF with mononuclear pleocytosis, and positive antigen detection (PCR or immunocytochemistry) in the CSF. Postvaccinal distemper encephalitis can be suspected on the basis of the temporal association of these signs and vaccination.

Parasitic Infection

Lower motor neuron spinal cord signs in a puppy with severe muscle involvement, spastic hind limbs, high CK activity, and eosinophilia can be diagnosed as a likely protozoal infection. Muscle biopsies also might be helpful in these cases, and parasites might be seen histopathologically. In adult dogs with multifocal signs and suspicion of a granulomatous lesion, MRI findings, a positive PCR for *neospora caninum* and high antibody titers directed against this microorganism all support the diagnosis of neosporosis.

Inflammatory Lesions of Unknown Origin

The findings in a young dog of acute fever, cervical hyperesthesia, neutrophilia, and massive pleocytosis with neutrophils in the CSF are characteristic of SRMA. In about 90% of cases a combined elevation of IgA in CSF and serum is detected. Contrast enhancement in MRI might be evident within the meninges.

Pug encephalitis probably can be diagnosed with reasonable certainty on the basis of breed, history, and occurrence of seizures. In breed-specific encephalitides, imaging techniques showing the presence of necrotic lesions are helpful.

Unfortunately, these “typical” cases account for less than half of all dogs with inflammatory/infectious diseases of the CNS. In the remaining dogs the differential diagnosis is a challenge, especially in adult and older dogs. It may be difficult to distinguish GME from inflammatory disease caused by distemper unless high numbers of neutrophils are present in the CSF. In this case, the diagnosis of GME will also need to be differentiated from chronic protracted steroid responsive meningoarthritis (SRMA); as both diseases increase CSF cell counts and are also steroid responsive. If a purely mononuclear pleocytosis is present, all relevant viral diseases must be considered in the differential diagnosis. MRI is helpful in cases of suspect GME, particularly if multifocal contrast-enhancing lesions are seen.

In summary, in typical cases of inflammatory disease of the CNS, the diagnosis will be made according to the following diagnostic scheme:

- Clinical examination: extraneural signs
- Neurologic examination: multifocal lesions
- Blood and urine examinations
- Imaging techniques (extraneural lesions)
- CSF examination (protein content, total and differential cell count)
- MRI, ev. CT scan (multifocal contrast-enhancing lesions)
- Antigen determination
- Antibodies (only with follow-up examination and rising titers).

Obviously a number of these studies require general anesthesia and careful planning. In many cases referral to a specialist with capability for advanced diagnostics is needed and should not be delayed less the patient deteriorate during a course of empiric therapy.

TREATMENT

Bacterial Infection

In bacterial meningoencephalitis extraneural lesions should be sought and treated appropriately (e.g., surgery). In the acute phase of encephalitis steroid treatment can be given once at the beginning (e.g., dexamethasone 0.15 mg/kg intravenously [IV], subcutaneously [SC], PO). Some authors state that there is an advantage when steroids are given before antibiotic treatment is started to reduce high intracranial pressure and brain edema (15 to 20 minutes before starting antibiotics) (Messer et al., 2006). This concept has been extrapolated from experiments on rabbits or is described for treatment of bacterial meningoencephalitis in humans (van de Beek et al., 2007). In small animals large studies are missing, and only case reports support this notion. In addition, steroid treatment is still under debate; for example, delayed steroid treatment 12 to 24 hours after the application of antibiotics shows no beneficial effect. Glucocorticoid treatment before diagnostic workup is contraindicated. Antibiotics should be started directly once the diagnosis is strongly suspected. Ideally antimicrobials are chosen after susceptibility testing. Since there is no time to wait for sensitivity testing or isolation of the microorganism, treatment has to be started empirically. Drugs prescribed should either have a good penetration through the blood-brain barrier or demonstrate efficacy against bacteria commonly found in the hospital setting. For gram-positive bacteria ampicillin (5 to 22 mg/kg q6h IV), cephalosporins (cephalexin 20 mg/kg q8h PO), trimethoprim-sulfonamide (15 to 20 mg/kg q8–12h IV or PO) and minocycline (5 to 12 mg/kg q12h IV or PO) are recommended. For gram-negative bacteria, in addition to the drugs mentioned previously, metronidazole (10 to 15 mg/kg q8h PO), chloramphenicol (40 to 50 mg/kg q6–8h PO) and gentamycin (2 mg/kg q8h IV, intramuscularly [IM]) can be applied. During bacterial encephalitis the blood-brain barrier permeability is increased, which increases the delivery of antibacterial drugs. Since it will not be known which bacteria are causing the disease

initially, a combination of drugs such as cephalosporins-metronidazole or ampicillin-chloramphenicol is frequently recommended. In addition, supportive treatment such as fluid therapy in dehydrated patients, external cooling for hyperthermia, or analgesia in animals with hyperesthesia is initiated. Pharmacologic treatment of fever is only recommended in cases with extremely high body temperatures. Decrease in the body temperature is a useful indicator for successful antimicrobial treatment. Seizures are treated with phenobarbital.

Viral Encephalitis

Currently there are no specific antiviral treatments for viral encephalitis. Therefore treatment in viral encephalitis mainly has to be supportive. Secondary bacterial infections are treated with antimicrobial drugs and nonspecific supportive therapy such as fluid therapy and administration of B-vitamins can be considered. Extraneural signs are treated with supportive therapy and good nursing care. Seizures are treated with phenobarbital. Some studies have been performed using immunomodulators such as feline interferon- ω ; however, no controlled studies have proven efficacy in vivo.

Parasitic Infection

Treatment of toxoplasmosis and neosporosis should start early in the course of the disease and last for 4 to 8 weeks. Information regarding the efficacy of such treatment efforts is limited. Adult dogs seem to respond better than puppies with muscle contraction. In case of muscular involvement clindamycin (15 to 22 mg/kg q12h PO, SC) is recommended. When the CNS is affected, trimethoprim-sulfonamide (15 to 20 mg/kg q12h PO) is given. A combination of both drugs is useful. Vitamin B substitution should be considered (folic acid at 1 mg/day or Brewer's yeast 100 mg/kg q24h PO). In addition, pyrimethamine (for *neosporea* with trimethoprim-sulfonamide 1 mg/kg q24h PO for 28 days) can be given in dogs, with consideration of potentially severe side effects such as anorexia, vomiting, depression, and bone marrow depression. Monitoring of CBC and platelet counts is recommended if pyrimethamine is administered.

Mycotic Infection

Antifungal drugs are used to treat systemic mycoses. The prognosis for mycotic involvement of the CNS is poor, but treatment should be initiated because it can be curative in immunocompetent animals. In immunocompromised animals infection may persist. Long-term treatment for 1 to 9 months or longer is necessary. CNS involvement by cryptococcosis is treated in cats and dogs with amphotericin B (0.5 mg/kg 3 times/week IV, SC), ketoconazole (dogs: 5 to 15 mg/kg q12h PO; cats: 50 mg total q24h PO or q48h if toxicity occurs), itraconazole (dogs: 10 mg/kg q24h PO; cats: 10 to 20 mg/kg q24h PO), or fluconazole (dogs and cats: 5 to 15 mg/kg q12–24h PO). It is advisable to consult a specialist when considering therapeutic options. In general, cats with CNS involvement seem to show a better recovery if treated with a combination of amphotericin B

and fluconazole. For most dogs the administration of amphotericin B is recommended; itraconazole is given as maintenance therapy after an initial treatment with amphotericin B. In dogs with extradural granuloma, surgical removal of the lesions might support medical treatment. Treatment of fungal infections remains a challenge for the veterinarian. Individual treatment schedules must be constructed for each patient, considering toxic side effects of medication, costs, and other underlying diseases such as feline leukemia virus infection in cats.

Inflammatory Lesions of Unknown Origin

Steroid-Responsive Meningitis-Arteritis

Treatment of SRMA is centered on antiinflammatory therapy. If initial signs are mild and neutrophilic pleocytosis is not higher than 100 cells/ μ l in CSF, nonsteroidal anti-inflammatory drugs might be used if the animal is carefully monitored. After the first relapse, when symptoms become worse, or when CSF analysis shows a massive pleocytosis, long-term treatment with prednisolone for at least 6 months must be initiated. The dosage is adjusted based on careful monitoring of clinical signs and adverse effects. Prednisolone is given initially at a dosage of 4 mg/kg q24h PO for 1 or 2 days; thereafter the dosage is 2 mg/kg q24h for about 1 to 2 weeks followed by 1 mg/kg q24h. The dogs are reexamined, including a CSF tap and blood profile, every 4 to 6 weeks after beginning therapy. As soon as the neurologic examination and CSF are found to be normal, the steroid dosage can be reduced to half of the previous until a dosage of 0.5 mg/kg q48h or q72h is reached. If pleocytosis persists, the same dosage should be continued. After about 6 months of therapy, if the patient appears clinically normal and demonstrates a normal CSF tap and blood profile for two consecutive examinations, the treatment is stopped. In long-standing cases, the same regimen is started from the beginning. If the dog does not respond sufficiently to therapy with prednisolone alone, immunosuppressive drugs such as azathioprine may be used in combination with steroids. It appears useful to azathioprine treatment every other day with steroids, with both drugs given every other day. Azathioprine may be prescribed at a dosage of 1.5 to 2 mg/kg q48h PO. Since neutrophils are an important cell population in SRMA, prednisolone is still a useful drug because of its broad-spectrum ability to suppress inflammation.

Often antibiotics are administered at the onset of treatment for SRMA because a bacterial infection cannot be excluded without analysis and culture of the CSF. Furthermore, protection against ulceration in the gastrointestinal tract should always be considered with long-term corticosteroid treatment. Owners should be advised that therapy with high doses of corticosteroids can lead to serious complications; treatment is not tolerated in about 5% of the dogs. In addition to serious complications, nonlife-threatening side effects such as polyuria, polydipsia, polyphagia, and weight gain are observed. Therefore individual management and monitoring of patients are the most important factors to provide successful patient management.

Pug Dog Encephalitis/Breed Specific Encephalitis

There is no treatment for this disease. Glucocorticoids do not alter the course of this necrotizing encephalitis

in confirmed cases, and antiepileptic drugs are often ineffective in controlling seizures.

GME/Encephalitis of Unknown Origin

It is difficult to definitively diagnose GME without histopathology. Since obtaining a brain biopsy is not always possible, both GME and encephalitis of unknown origin should be considered as potential causes of CNS inflammation. These are discussed together.

Only a few treatment studies are available for management of GME, and a definitive diagnosis was often unavailable for the reported cases. Therefore our current knowledge of therapy relates to treatment of the so-called *encephalitis of unknown origin* or of dogs with presumptive antemortem diagnosis of GME.

There is no specific therapy for GME, although improvement has been observed following administration of glucocorticosteroid or other immunosuppressive drugs. Glucocorticoid treatment frequently provides only temporary improvement, and side effects can limit usefulness. Typical dosages include prednisone or prednisolone 0.25 to 2 mg/kg q12–24h PO or dexamethasone 0.2 to 0.4 mg/kg q24h PO, IM, SC, depending on clinical improvement and side effects. Additional medications such as cytosine arabinoside (100 mg/m² q24h IV, SC [Zarfoss et al., 2006]); cyclosporine (3 to 6 mg/kg q12h PO [Adamo and O'Brien, 2004]) or procarbazine (25 to 50 mg/m² q24h PO [Coates et al., 2007]) may be considered as adjunctive treatments or treatment on their own. With this array of choices, it is useful to consult a neurologist for additional perspective when treating these patients.

CSF reexaminations and clinical monitoring, including regular blood examinations, are necessary. In case of myelosuppression from procarbazine, some authors recommend reducing the dosage by 50% or discontinuing therapy, depending on the severity of adverse effects (Coates et al., 2007). Azathioprine may be given at a dosage of 2 mg/kg q24–48h PO in addition to glucocorticosteroids, allowing for reduction in the amount of these drugs in case of severe side effects. In my experience it seems useful to alternate azathioprine treatment every other day with corticosteroids as discussed previously in this chapter. Radiation therapy is thought to have some efficacy in dogs with focal GME. Controlled multicenter studies should be conducted to learn more about the nature of this group of diseases and their treatment.

CHAPTER 234

Treatment of Cerebrovascular Disease

LAURENT S. GAROSI, *Higham Gobion, England*
SIMON R. PLATT, *Athens, Georgia*

CEREBROVASCULAR ACCIDENT (OR STROKE)

There has been a good deal of confusion in the veterinary literature regarding the terms *cerebrovascular disease*, *cerebrovascular accident*, and *stroke*. Cerebrovascular disease refers to any abnormality of the brain caused by a pathologic process compromising blood supply. Pathologic processes that may result in cerebrovascular disease include occlusion of the lumen by a thrombus or embolus, rupture of a blood vessel wall, a lesion or altered permeability of the vessel wall, and increased viscosity or other changes in the quality of the blood. Stroke or cerebrovascular accident (CVA) is the most common clinical presentation of cerebrovascular disease and is defined as a sudden onset of nonprogressive focal brain signs secondary to cerebrovascular disease. By convention these signs must persist for more than 24 hours to qualify for the diagnosis of stroke, which is usually associated with permanent damage to the brain. If the clinical signs resolve within 24 hours, the episode is called a *transient ischemic attack*. From a pathologic point of view, a CVA falls into one or two broad categories: 1) ischemia with or without infarction secondary to obstructed blood vessels, or 2) hemorrhage caused by rupture of the blood vessel wall.

Ischemic Stroke

With limited stores the brain relies on a permanent supply of glucose and oxygen to maintain ionic pump function.

When perfusion pressure falls to critical levels, ischemia develops, progressing to infarction if hypoperfusion persists long enough. An infarct is an area of compromised or necrotic brain parenchyma caused by a focal occlusion of one or more blood vessels. It may be caused by either vascular obstruction that develops within the affected vessels (thrombosis) or obstructive material that originates from another vascular bed and travels to the brain (thromboembolism). Depending on the size of vessel involved, infarcts can be the consequence of small-vessel disease (i.e., superficial or deep perforating artery), which gives rise to a lacunar infarct; or large-vessel disease (a major artery of the brain or its main branches), which gives rise to a territorial infarct. Two distinct regions can be distinguished: the core where ischemia is severe and infarction develops rapidly; and the penumbra that surrounds the core and demonstrates a less severe reduction of cerebral blood flow (CBF), allowing longer durations of ischemic stress to be tolerated. The relative volume of pathology within these two regions changes as the infarct evolves. The factors favoring evolution of the penumbra to irreversible brain injury are multiple and complex. The time window during which the penumbra is no longer viable depends on the degree of blood flow reduction, the region of the brain involved, and the individual. In the penumbra neurons are still viable but at risk of becoming irreversibly injured. Penumbra tissue has the potential for recovery and therefore is the target for interventional therapy in acute ischemic stroke.

Ischemic strokes have been reported infrequently in veterinary publications when compared with human medical literature. Most reports have been based on post-mortem results in dogs that either died or were euthanized as a result of the severity of the ischemic stroke and/or the suspected underlying cause of the stroke. This retrospective reporting may affect the prevalence and type of underlying causes identified in canine CVA, because only the most severely cases are likely to be reported. In a similar vein, dogs in which infarction occurred secondarily to a disease with a poor prognosis would also die or be euthanized. Suspected underlying causes identified in histopathologically confirmed cases included septic thromboemboli, atherosclerosis associated with primary hypothyroidism, migrating parasite or parasitic emboli (*Dirofilaria immitis*), embolic metastatic tumor cells, intravascular lymphoma, and fibrocartilaginous embolism. In our magnetic resonance imaging (MRI)-based study a concurrent medical condition was detected in just over 50% of dogs affected by brain infarcts. Hypertension was documented in 30% of dogs. Of these dogs, chronic kidney disease and hyperadrenocorticism were the most commonly suspected underlying causes for the hypertension. No underlying cause could be identified antemortem in nearly half of the dogs. An infarct of unknown origin is called cryptogenic. No age, sex, or breed predisposition was identified. However, cavalier King Charles spaniels and greyhounds appeared overrepresented.

Hemorrhagic Stroke

In hemorrhagic stroke blood leaks from the vessel directly into the brain, forming a hematoma within the brain parenchyma or into the subarachnoid space. The mass of clotted blood causes physical disruption of the tissue and pressure on the surrounding brain. This alters central nervous system volume/pressure relationships with the possibility of increasing intracranial pressure (ICP) and decreasing CBF. In contrast to the high incidence in humans, intracerebral hemorrhage resulting from spontaneous rupture of vessels is considered rare in dogs. Secondary hemorrhage in dogs has been associated with rupture of congenital vascular abnormalities, primary and secondary brain tumors, inflammatory disease of the arteries and veins, intravascular lymphoma, brain infarction (hemorrhagic infarction), or impaired coagulation. Nontraumatic subarachnoid hemorrhage has been reported in dogs but remains very rare. This is in contrast to humans patients in whom aneurysmal rupture of blood vessels is the most common underlying cause of hemorrhagic stroke.

CLINICAL PRESENTATION

In all forms of stroke the denominative feature is the temporal profile of neurologic events. The abruptness with which the neurologic deficits develop is highly suggestive that the disorder is vascular. This is then followed by an arrest and then regression of the neurologic deficit in all except fatal strokes. Worsening of edema (associated with the secondary injury phenomenon) can result in progression of neurologic signs for a short

period of 24 to 72 hours. Intracranial hemorrhage can be an exception to this description, presenting with a more progressive onset over a very short period of time. Clinical signs usually regress after 24 to 72 hours; this is attributable to diminution of the mass effect caused by hemorrhage with subsequent reorganization or to edema resorption. Neurologic deficits usually refer to a focal anatomic diagnosis and depend on the neurolocalization of the vascular insult (telencephalon, thalamus, midbrain, pons, medulla, cerebellum). Infarction of an individual brain region is associated with specific clinical signs that reflect the loss of function of that specific region. With hemorrhagic stroke the total clinical picture is different because the hemorrhage usually involves the territory of more than one artery, and pressure effects cause secondary signs. Neurologic signs are largely related to increasing ICP, which gives rise to nonspecific signs of forebrain or brainstem disease. Fundus examination is important and may reveal findings such as tortuous vessels (suggestive of systemic hypertension), hemorrhage (suggestive of coagulopathy or systemic hypertension), or papilledema (suggestive of elevated ICP).

Imaging studies of the brain (computed tomography, conventional and functional MRI) are necessary to confirm the suspicion of stroke, define the vascular territory involved and the extent of the lesion, and distinguish between ischemic and hemorrhagic stroke. Imaging studies are also necessary to rule out other causes of neurologic deficit such as tumor, head trauma, and encephalitis. (See References and Suggested Reading for more details.)

Ancillary diagnostic tests in ischemic stroke should focus on evaluating the animal for hypertension (and underlying causes), endocrine disease (hyperadrenocorticism, hypothyroidism, hyperthyroidism, diabetes mellitus), kidney disease (especially protein-losing nephropathy), heart disease (a greater risk factor in cats with cardiomyopathy), and metastatic disease. In cases of ischemic strokes, D-dimer assays and antithrombin III evaluation should be routinely included in the screening tests for thromboembolic disease as a possible cause of ischemic stroke. D-dimer is considered to be more useful test for detecting thromboembolic disease in dogs when compared to traditional tests currently in use (platelet count and clotting times). In cases of hemorrhagic stroke, diagnostic tests should be targeted to screen the animal for a coagulation disorder (and underlying causes), hypertension (and underlying causes), and metastatic disease (particularly hemangiosarcoma).

TREATMENT AND PROGNOSIS OF STROKE

Once the diagnosis of a stroke has been made, any potential underlying disease should be identified and treated accordingly. Generally treatment of these patients aims to provide supportive care, maintain adequate tissue oxygenation, and manage neurologic and nonneurologic complications. Nursing management of a recumbent dog is vital to the success of more specific therapies. Such management includes prevention of decubital ulceration, aspiration pneumonia, and urine scald, in addition to physical

therapy and enteral nutrition provision. More specific therapies are aimed at preventing further neurologic deterioration.

Treatment of Ischemic Stroke

Treatment of an ischemic stroke revolves around three principles: monitoring and correcting basic physiologic variables (e.g., oxygen level, fluid balance, blood pressure, body temperature), inhibiting the biochemical and metabolic cascades subsequent to ischemia to prevent neuronal death (the concept of neuroprotection), and restoring or improving CBF by thrombolysis in the presence of a thrombus. The potentially salvageable portion of the ischemic zone (ischemic penumbra) is the presumed therapeutic target for both thrombolytic and neuroprotective stroke therapy. The time period during which injury may be reversible is called the therapeutic window. It is estimated that this "window of opportunity" is approximately 6 hours before irreversible neurologic damage occurs. Fortunately the vast majority of ischemic stroke patients have no major difficulty maintaining their airways, breathing efforts, or circulatory competence early in their clinical course.

There is some controversy surrounding the management of hypertension in the setting of an ongoing acute ischemic stroke. While a potential risk factor for a CVA, hypertension also can develop as a physiologic response to a stroke to ensure an adequate cerebral perfusion pressure (CPP) in the penumbra of the infarct. Elevated blood pressure can persist for up to 72 hours after the onset of injury. Maintenance of systemic arterial blood pressure within the physiologic range is essential, and aggressive lowering of blood pressure should be avoided during the acute stages unless the patient is at a high risk of end-stage organ damage (systolic blood pressures remaining above 180 mm Hg). In such cases hypertension often can be controlled with an angiotensin-converting enzyme inhibitor such as enalapril (0.25 to 0.5 mg/kg BID) or benazepril (0.25 to 0.5 mg/kg BID) and/or calcium channel blockers such as amlodipine (0.1 to 0.25 mg/kg once or twice daily). Amlodipine is more effective in severe hypertension.

There is no evidence that glucocorticoid treatment provides any beneficial neuroprotection in stroke. Aside from the lack of proven benefit in veterinary stroke patients, the use of glucocorticoids may increase the risk of gastrointestinal complications and infection. Treatment strategies for ischemic stroke considered in humans using other neuroprotective agents (N-methyl-D-aspartate [NMDA] antagonists, Ca²⁺ channel blockers, sodium channel modulators) or antiplatelets and thrombolytic therapy remain to be evaluated clinically in dogs. Although these neuroprotective agents have resulted in a dramatic decrease in the size of stroke lesion in experimental animal models, they have either failed to prove their efficacy in clinical trials or are awaiting further investigation. At the time of writing, there are no definitive data in humans or animals to confirm a significant improvement in clinical outcome in patients with acute ischemic stroke treated with unfractionated heparin as anticoagulant therapy. Despite conflicting results regarding its efficacy, intravenous recombinant tissue plasminogen activator (tPA) is

sometimes used in human ischemic stroke patients if it can be given within the first 3 hours. This critical time window makes the use of thrombolytic treatment unrealistic in veterinary neurology. Furthermore, this type of treatment carries a significant risk of intracranial hemorrhage following treatment. Antiplatelet therapy with low-dose aspirin (0.5 mg/kg PO SID) or perhaps clopidogrel can be used prophylactically to prevent clot formation in proven cardiac sources of an embolus.

Treatment of Hemorrhagic Stroke

The medical management of dogs with intracranial hemorrhage commonly includes stabilization of the patient (airway protection, monitoring and correction of vital signs); assessment and monitoring of the neurologic status; determination and treatment of potential underlying causes of the hemorrhage; and assessment for the need for specific treatment measures, including management of raised ICP. The risk of neurologic deterioration and cardiovascular instability is highest during the first 24 hours after the onset of an intracranial hemorrhage as the space-occupying lesion slowly expands and cerebral vasogenic edema develops. Therefore careful monitoring, including assessment of vital parameters (e.g., oxygen levels, fluid balance, blood pressure, body temperature) and neurologic status, is essential during this initial period. Unfortunately clinical signs of raised ICP are often delayed, inconsistent, and nonspecific. The size of an intracranial hematoma can be difficult to estimate from the neurologic examination alone. ICP monitoring systems are used frequently in human hospitals, but their use is very limited in veterinary hospitals. As a hematoma develops initially, ICP may be maintained at a constant as a result of a system of compensation. Within the closed space of the skull a change in the volume of one intracranial constituent (brain tissue, arterial blood, venous blood, or cerebrospinal fluid) is balanced by a compensatory change in another incompressible constituent. This is the Monroe-Kellie doctrine, which explains why some animals with large intracranial bleeds develop substantial increases in ICP at the time of herniation. The exhaustion of the compensating mechanisms for an intracranial space-occupying lesion implies that any further increase in the volume of the hematoma will produce a massive rise in ICP, and clinically this can be associated with herniation. Because of mechanical autoregulation, CBF remains constant, even though the CPP may vary between 40 and 120 mm Hg. The normal autoregulation of CBF may be impaired following a CVA, causing blood flow to damaged regions to become directly dependent on systemic blood pressure. Such animals may be unable to compensate for reductions in mean arterial blood pressure, causing decreased CPP in the presence of increased ICP. This emphasizes the importance of maintaining systemic blood pressure. In these circumstances systemic hypotension can result in inadequate perfusion of the brain, which leads to cerebral ischemic and secondary neuronal injury. Hypovolemia should be recognized and treated with volume expansion using crystalloids, colloids, or hypertonic saline. Central venous pressure monitoring can be useful as an aid to assessing the effectiveness of volume resuscitation, assuming cardiac function is

otherwise normal. The use of glucose-containing solutions is discouraged since hyperglycemia has been shown to correlate with poor outcome in human stroke patient. As such, blood glucose should be monitored from the time of presentation. However, moderate levels of hypertension should not be treated because systemic hypertension may be secondary to the intense reflex sympathetic response to intracranial hypertension, which is a compensatory mechanism to maintain cerebral perfusion. As for ischemic stroke, attempts to lower and normalize the blood pressure should be reserved for animals at a high risk of end-stage organ damage (systolic blood pressures remaining above 180 mm Hg) and/or animals with severe ocular manifestations of hypertension such as retinal detachment or intraocular hemorrhage. Treatment recommendations for lowering blood pressure are detailed in the preceding section on treatment of ischemic stroke.

There is no evidence in humans to support the routine use of oxygen for the treatment of hemorrhagic stroke in the absence of hypoxia. In a rapidly deteriorating animal hyperventilation can be used temporarily to reduce ICP. The aim of hyperventilation is to reduce cerebral blood volume and hence ICP by causing a hypocapnic vasoconstriction. However, excessive hyperventilation can be accompanied by a reduction in global cerebral blood flow, which may drop below ischemic thresholds; therefore it is not a recommended therapy unless the P_{aCO_2} can be closely monitored with capnography or arterial blood gas analysis.

Mannitol has been used traditionally to treat intracranial hypertension associated with pathologies such as head trauma, brain tumors, or encephalitis. There is insubstantial evidence to suggest that mannitol exacerbates intracranial hemorrhage; therefore osmotic diuretics are used routinely in the control of ICP in human patients with known intracranial hemorrhage. Mannitol therapy (0.25 to 1 g/kg intravenously over 10 to 20 minutes up to every 8 hours) may be initiated to treat suspected elevated ICP secondary to hemorrhagic stroke. The main effect of mannitol is to enhance CBF by reducing blood viscosity. Surgical evacuation of the hematoma can be used in dogs

with large hematomas (mostly subarachnoid) and a deteriorating neurologic status.

PROGNOSIS

The prognosis for ischemic or hemorrhagic stroke depends overall on the initial severity of the neurologic deficit, the initial response to supportive care, and the severity of the underlying cause if one has been identified. Fortunately most cases of ischemic stroke recover within several weeks with only supportive care. In a recent retrospective study of 33 dogs with MRI or necropsy evidence of brain infarction, there was no association between the region of the brain involved (telencephalic, thalamic/midbrain, cerebellum), the type of infarction (territorial or lacunar), and the outcome. However, dogs with a concurrent medical condition had a significantly shorter survival time than those with no identifiable medical condition. Dogs with a concurrent medical condition also were significantly more likely to suffer from recurrent neurologic signs caused by subsequent infarcts.

Treatment of Intracranial Tumors

JILL NARAK, *Auburn, Alabama*

TODD W. AXLUND, *Akron, Ohio*

ANNETTE N. SMITH, *Auburn, Alabama*

Interacranial tumors cause a devastating clinical picture, with signs that may include seizures, behavior changes, proprioceptive deficits, altered mentation, vestibular disease, and other cranial nerve abnormalities. Clinical signs are caused by the destruction of normal brain tissue that accompanies tumors; but patients also deteriorate because of secondary effects, including peritumoral edema and hemorrhage, leading to increased intracranial pressure and potentially brain herniation. Intracranial neoplasia affecting dogs and cats can arise from primary or secondary sources. Primary tumors arise directly from intracranial structures and include meningioma, glial tumors, neuroepithelial tumors, neural tumors, pituitary gland tumors, pineal gland tumors, and germ cell tumors. Secondary tumors arise from extracranial structures and include extension of nasal or skull tumors and metastatic neoplasia.

All intracranial tumors carry a poor prognosis; however, it is often difficult to discuss prognoses because treatment is sometimes initiated without a definitive diagnosis. Definitive treatment relies on an accurate histopathologic tumor diagnosis, although correlations between tumor appearance on magnetic resonance imaging (MRI) and histopathologic diagnoses have been reported (Kraft et al., 1997; Snyder et al., 2006). The patient's prognosis is related to tumor biologic behavior, as well as severity and progression of clinical signs. Without treatment intracranial tumors offer a grave prognosis.

DEFINITIVE THERAPIES

Definitive treatments include surgical excision, irradiation, and chemotherapy. These therapies aim to reduce or eradicate the tumor mass and decrease its secondary effects such as peritumoral edema, hemorrhage, and intracranial hypertension.

Surgical Excision

Surgical Approaches and Considerations

Surgical removal of an intracranial tumor achieves many treatment goals, including decompression and reduction of intracranial pressure and obtaining a histopathologic diagnosis, which allows for prognostication and additional treatment planning in the case of subtotal resection. Surgical approaches include rostral tentorial, caudal tentorial, transfrontal, and suboccipital craniotomies or craniectomies; combinations of these approaches may be used. The tumor size, degree of invasiveness, and

location determine whether or not surgical removal is a viable option; and it guides the neurosurgeon's choice of approach. Intraaxial tumors, which are located within the brain parenchyma, are more difficult to remove compared with extraaxial tumors. In addition, approaches to the caudal fossa are difficult and seldom attempted because of the possibility of inducing iatrogenic trauma to the brainstem and causing severe clinical signs in the patient.

In most cases the goal of surgery is removal of the entire mass. Tumor removal can be achieved using a combination of sharp and blunt dissection, or an ultrasonic aspirator can be used. Adequate dissection can be difficult because many tumors are not well delineated from normal tissue, and adjacent normal brain tissue may be compromised because of peritumoral edema or hemorrhage.

The dura mater must be incised or removed to obtain adequate visualization of the underlying brain structures. The defect can be closed using a graft (synthetic or fascial), or it may be left open. In dogs and cats cerebrospinal fluid (CSF) does not typically cause complications when leaked into the surrounding tissues (Niebauer, Dayrell-Hart, and Speciale, 1991). To protect the underlying brain, the skull defect is usually replaced when using a transfrontal or radical rostral tentorial approach; replacement is not necessary when using other approaches.

To assess the completeness of resection, the neurosurgeon can check the gross surgical margins intraoperatively using a sterile ultrasound technique or after surgery using MRI. If necessary, the surgeon can reoperate immediately to remove more tumor tissue or address life-threatening postoperative hemorrhage or cerebral swelling. Microscopic surgical margins can be assessed intraoperatively by histopathology using cryosectioned biopsy samples.

A tissue diagnosis may also be obtained using the less invasive computed tomography (CT)-guided biopsy; stereotactic or freehand CT-guided biopsy may be performed. Both techniques may induce iatrogenic hemorrhage; and, if necessary, a craniotomy will need to be performed to manage hemostasis.

Anesthetic Considerations

Intracranial tumor patients typically are older animals, and concurrent disease may be present. Preanesthetic screening, including complete blood count (CBC), serum biochemistry profile, urinalysis, thoracic radiography, and abdominal ultrasound, is indicated both to ensure the general health of the patient and to identify metastatic or other systemic disease, which could change the management approach.

In addition, these patients often have elevated intracranial pressure; thus the anesthetist should take measures to avoid or reduce intracranial hypertension, including maintaining normotension (systolic blood pressure 110 to 160 mm Hg or mean arterial pressure 80 to 110 mm Hg), eucardia (35 to 45 mm Hg), and analgesia. Inhalant anesthetics increase cerebral blood flow, which can lead to or potentiate intracranial hypertension; injectable anesthetics such as propofol and fentanyl can be used to decrease the requirement of inhalant anesthetics. Diuretics and glucocorticoids may be given to decrease brain edema (Table 235-1). Intracranial surgery can be associated with intraoperative hemorrhage; thus one should be prepared for a blood transfusion. After surgery the patient should be allowed to recover gradually from anesthesia. It is critically important to avoid excitement on recovery, and additional sedation may be required. Analgesia should be continued and titrated to the patient's needs.

Intraoperative and Postoperative Considerations

Intraoperative complications include hemorrhage and hypotension, intracranial hypertension, and air embolism. Postoperative infection may be of concern after transfrontal craniotomy because the approach involves incision through the contaminated frontal sinus. However, postoperative infection is not a typical complication associated with intracranial surgery, possibly because of the routine use of perioperative antibiotics (see Table 235-1). Intracranial hypertension is a concern following surgery, and patient

positioning can aid in keeping intracranial pressure in the normal range. Intracranial pressure can be measured directly, or it can be monitored indirectly by observing for changes associated with intracranial hypertension, including the Cushing's response (systemic hypertension with bradycardia) and changes in pupil size and symmetry. The patient's head should be elevated (approximately 30 degrees), jugular occlusion should be avoided (e.g., no jugular venipuncture or neck leads), and pain and excitement should be prevented. If necessary, diuretics and/or glucocorticoids can be continued in the postoperative period. If the patient is recumbent, urinary catheterization may be necessary. Care should be taken to keep the patient clean and dry, and appropriate bedding with frequent rotation or placement in a sling to prevent the formation of decubital ulcers is required. To avoid aspiration pneumonia the patient should be given nothing per os for 24 hours postoperatively. Nutritional and intravenous fluid support is indicated in a patient who cannot maintain adequate nutrition orally.

Meningioma

Meningiomas are usually easily accessible to the neurosurgeon since they are often extraaxial masses. However, meningiomas located along the brainstem or those located on the falx cerebri or tentorium cerebelli or along the lateral ventricles may be more difficult to access.

Surgical removal of feline meningiomas may be curative since the entire mass can often be removed in total; surgical excision is the treatment of choice for feline men-

Table 235-1

Medications Used in the Treatment of Intracranial Tumors

Drug	Dose	Use/Indication
Carmustine	50 mg/ml q6wk IV (over 15-20 min)	Nitrosurea chemotherapeutic agent; may be used to treat meningioma and glioma
Cefazolin	22 mg/kg q90min IV	Perioperative antibiotic
Cytosine arabinoside	20-100 mg/m ² q1wk intrathecally	Chemotherapeutic agent, used to treat CNS lymphoma
Diazepam and midazolam	0.5 mg/kg as needed IV; or 2 mg/kg as needed per rectum	Anticonvulsant used in emergency management of status epilepticus or cluster seizures
Dimenhydrinate	Dog: 25-50mg 8-24h PO Cat: 12.5 mg q8-24h PO	Antihistamine (antiemetic used for vestibular disease)
Hydroxyurea	20 mg/kg q24h PO	Chemotherapeutic agent; may be used to treat meningioma
Lomustine	Dog: 60-90 mg/m ² q3-6wk PO Cat: 50-60 mg/m ² q6wk PO	Nitrosurea chemotherapeutic agent; may be used to treat meningioma and glioma
Mannitol	0.5-1 g/kg q4h or as needed IV	Osmotic diuretic used to decrease brain edema and lower intracranial pressure
Meclizine	25 mg/dog and 12.5 mg/cat q24h PO	Antihistamine (antiemetic used for vestibular disease)
Methylprednisolone sodium succinate	30 mg/kg once IV; or 100 mg/kg given over 24 hours IV	Glucocorticoid used to decrease peritumoral brain edema and lower intracranial pressure
7.5% NaCl	5-20 ml/kg as needed IV	Osmotic diuretic used to decrease brain edema and lower intracranial pressure
Phenobarbital	Loading dose: 5 mg/kg as needed IV (up to 20 mg/kg total) Maintenance dosage: 2-3 mg/kg q12h PO	Anticonvulsant
Potassium bromide	Loading dose: 70 mg/kg q12h PO Maintenance dosage: 20 mg/kg q12h PO	Anticonvulsant
Prednisone	0.5-1 mg/kg q12h PO	Glucocorticoid used for supportive therapy of intracranial tumors

CNS, Central nervous system; IV, intravenously; PO, orally.

Table 235-2

Comparison of Median Survival Times in Dogs and Cats With Intracranial Tumors Treated With Surgical Excision And Irradiation*

Authors	Tumor Type	Number of Patients	Treatment Type	Median Survival Time (Days)
Troxel et al.	Meningioma	34 cats	Surgical excision	685
Greco et al.	Meningioma	17 dogs	Surgical excision	1254
Axlund et al.	Meningioma	14 dogs	Surgical excision	210
	Meningioma	12 dogs	Surgical excision followed by irradiation	495
Brearley et al.	Extraaxial tumors	41 dogs	Irradiation	347
	Intraaxial tumors	34 dogs	Irradiation	282
	Pituitary tumors	8 dogs	Irradiation	147

*Determined by the Kaplan-Meier Product Limit Method.

ingiomas. Troxel and associates (2003) reported that cats treated with surgical removal of meningiomas had a significantly longer survival time than cats treated by any other modality (Table 235-2). Niebauer, Dayrell-Hart, and Speciale (1991) reported that 50% of cats were alive 2 years after surgery.

Canine meningiomas are more difficult to remove totally. Histologically these tumors tend to be more aggressive and invasive than the feline form. Thus surgical removal often leaves behind microscopic disease and should be followed with radiation therapy or chemotherapy. Greco and colleagues (2006) reported that histopathologic tumor subtype influenced prognosis: transitional and meningothelial meningiomas yielded higher median survival times than fibroblastic, anaplastic, and psammomatous meningiomas. Théon and associates (2000) found that a high tumor proliferative index, noted on immunohistochemical analysis of histologic tumor sections, was a significant prognostic indicator for tumor progression in dogs with meningioma.

Glioma

Surgical removal can be helpful to debulk and histopathologically diagnose gliomas. However, gliomas are invasive tumors, and it is difficult to obtain clean margins. These tumors are typically highly vascular; and, because of their deep location, surgical resection may cause damage to normal brain parenchyma. Their location may also make them difficult to visualize at surgery; intraoperative ultrasound may be useful to delineate tumor margins. For these reasons surgical removal of gliomas is usually followed with radiation therapy.

Others

Pituitary microadenomas may be amenable to surgical removal, but macroadenomas typically are too large for excision. Radiation therapy is the treatment of choice for these tumors, although the prognosis is worse if neurologic signs are present. The pituitary height-to-brain area ratio is used to discriminate between pituitary microadenoma and macroadenoma and to determine ease of surgical removal. Traditionally a macroadenoma may be defined as a pituitary gland that is greater than 1 cm in height, although Meij and associates (1998) describe that in veterinary medicine a pituitary macroadenoma is defined when the pituitary

height-to-brain ratio is greater than 0.31. Techniques described for pituitary microadenoma removal include the transsphenoidal and ventral paramedian approaches.

Neuroepithelial tumors such as choroid plexus papillomas and ependymomas may be removed surgically; however, they are often located in difficult locations (in the ventricular system). As a result of their location, obstructive hydrocephalus may occur and exacerbate clinical signs. To relieve hydrocephalus, a viable option is the placement of a ventriculoperitoneal shunt; this procedure may or may not be combined with tumor removal.

Radiation Therapy

Radiation therapy (see Chapter 67) may be used as adjunct treatment to surgical excision; in fact, it may be most efficacious when combined with surgical tumor removal (see Table 235-2). Radiation therapy can also be used as sole therapy for intracranial tumors. Because of the potential morbidity associated with surgical removal of brainstem masses, the use of radiation as sole therapy is the treatment of choice for these tumors. The use of radiation as sole therapy is justified if surgical expertise is not available; however, radiation therapy also often requires referral to a specialty referral center. Megavoltage radiation is recommended, but orthovoltage has also been used. Radiation oncologists base treatment planning on the known or suspected tumor type and location, keeping in mind the acute and late side effects that may be induced by radiation therapy.

The goal of radiation therapy is to deliver a tumoricidal dose of radiation while sparing normal brain tissue. High doses of radiation improve control of brain tumors but put the patient at risk for radiation-induced brain necrosis; thus the risk-to-benefit ratio needs to be considered for each patient. Radiation-induced brain damage is the result of focal necrosis and local hemorrhage. Fractionation is a strategy used to avoid radiation-induced brain necrosis. This approach relies on the ability of normal tissue to repair itself between doses of radiation. Tumor cells have lost this ability for repair; thus the radiation doses are lethal to the tumor mass. Typical fractionation schedules call for three to five anesthetic episodes per week, which can be stressful to the typical geriatric brain tumor patient. Ideally, to avoid radiation-induced brain necrosis, treatments are delivered in fractions of less than 300cGy to reach a total dose of 45 to 50Gy.

Therapy may fail as a result of tumor recurrence or radiation-induced brain necrosis. Advanced imaging cannot distinguish between these processes, and both present with similar clinical signs; it can be difficult to know if a patient is deteriorating as a result of tumor progression or brain necrosis. A severe and rapid neurologic decline may be the result of radiation-induced brain necrosis, compared to a slowly progressive decline in neurologic status, which may represent tumor regrowth (Brearley et al., 1999). Ultimately though, this differentiation can be made only on postmortem examination. Brain is a late responding tissue; thus these radiation side effects may not be noted until months to years after treatment, and Spugnini and associates (2000) reported that only 5% to 20% of brain tumor patients survive to be at risk for these effects. Another late side effect to consider is new tumor growth induced by radiation, as noted in one report by Théon et al. (2000).

Acute side effects of radiation therapy in the brain can be seen weeks to months after therapy and include transient demyelination, which usually responds to anti-inflammatory doses of corticosteroids (see Table 235-1). Other acute side effects of radiation therapy depend on the treatment portal used and may include keratoconjunctivitis, corneal ulcers, mucositis, otitis externa, and dermatitis. Although these effects are not life threatening, they may cause debilitation in the short term and require appropriate management.

Stereotactic radiosurgery is a technique allowing for the precise delivery of radiation to the tumor while sparing adjacent normal brain tissue. Only one anesthetic episode is required because a sufficient dose of radiation is delivered to the tumor at once while only a fraction of that dose is delivered to normal brain tissue. This technique can be used for tumors of relatively small diameter and requires referral to an adequately equipped specialty center. Other techniques such as boron neutron capture therapy and brachytherapy have been attempted to deliver a precise dose of radiation to the tumor tissue.

Chemotherapy

Chemotherapy has been largely ineffectual in the treatment of brain tumors, but certain therapeutics deserve consideration. The blood-brain barrier is impermeable to large, hydrophilic compounds; most drugs are unable to penetrate the blood-brain barrier and therefore are unable to exert their tumoricidal effects on brain tumors. However, in the face of significant pathology, the blood-brain barrier may not be completely impenetrable, and some drug therapy may have limited success. To increase effectiveness of a chemotherapeutic drug, agents that increase blood-brain barrier permeability may be given (e.g., mannitol); however, this technique may also increase the toxic side effects of a chemotherapeutic drug and is generally not advised. To obtain maximum delivery into the central nervous system (CNS), agents can be directly injected into the subarachnoid space (intrathecal injection). Intratumoral injections of chemotherapy have been tried in humans and may be useful in delivering a precise dose of chemotherapy directly into the brain tumor; however, this is an invasive technique. Certain tumors are

considered to be relatively chemoresponsive (e.g., CNS lymphoma, medulloblastoma, oligodendroglioma), but chemotherapy may be considered for any patient with an intracranial tumor. Lymphoma of the CNS is considered to be nonsurgical and is instead treated with systemic and intrathecal chemotherapy. Chemotherapy is also used in the face of metastatic brain neoplasia; the protocol used depends on the primary tumor. Surgical debulking and radiation therapy may not be advised in the face of metastatic brain neoplasia because of the poor prognosis; however, these modalities can be offered as palliative therapy. Standard protocols for chemotherapy in the face of intracranial tumors have not been developed, but certain chemotherapeutics are discussed here.

Nitrosureas

Nitrosureas are highly lipophilic and obtain rapid passage across the blood-brain barrier. Lomustine (CeeNu, Bristol Labs Oncology) and carmustine (BiCNU, Bristol-Myers Squibb) are used as adjunct therapy for brain tumors (see Table 235-1). These agents have been used to treat glioma and meningioma with varying success. Side effects of the nitrosureas include myelosuppression; thus CBCs should be monitored weekly, beginning after the first week of treatment. Maximum myelosuppression may not occur until 4 to 6 weeks after treatment, and the effects (neutropenia and thrombocytopenia) may be cumulative. If the patient becomes neutropenic at $<1000 \times 10^3/\mu\text{l}$ but appears to be otherwise healthy, broad-spectrum oral antibiotics may be advised; if a patient is neutropenic at $<1000 \times 10^3/\mu\text{l}$ and displays signs of sepsis or systemic illness (lethargy, vomiting, diarrhea, or fever), the patient should be hospitalized and placed on broad-spectrum intravenous antibiotics while monitoring for progression of sepsis. Lomustine can also cause hepatotoxicity and nephrotoxicity; thus it is important to monitor serial serum biochemistry profiles. If evidence of toxicity is present, hepatic and renal function tests and/or abdominal ultrasound should be performed. It is important to note that the same hepatic microsomal enzymes induced by phenobarbital are necessary for generating the antineoplastic metabolites of lomustine; thus, before being treated with lomustine, the patient may need to be switched from phenobarbital to a different anticonvulsant such as potassium bromide.

Hydroxyurea

Hydroxyurea is a chemotherapeutic agent that also crosses the blood-brain barrier and may be useful in the treatment of intracranial tumors (see Table 235-1). Hydroxyurea has shown promise in treating humans with unresectable or recurrent meningioma, but there is no evidence demonstrating its efficacy in dogs or cats. The most serious side effect of hydroxyurea is myelosuppression; serial CBCs should be monitored.

Cytosine Arabinoside

Intrathecal delivery of cytosine arabinoside (Cytosar, Pharmacia & Upjohn) has been used in the treatment of CNS lymphoma when malignant cells are found in the CSF. Cytosine arabinoside may be delivered intrathecally (see Table 235-1). The chemotherapy is given 1 week

beyond an atypical lymphocyte-free CSF tap; three to six treatments are usually necessary. Intrathecal delivery of chemotherapy requires general anesthesia and the technical expertise to perform a CSF tap. Systemic chemotherapy is recommended in conjunction with intrathecal chemotherapy; protocols are discussed elsewhere. Response to treatment is usually weeks to months.

Others

The combination of procarbazine, lomustine, and vincristine has been used to treat certain types of human glioma. Temozolamide is an alkylating agent that has also been used with varying success in humans with glioma. Methotrexate has been used intrathecally to treat humans with CNS lymphoma. Studies need to be performed in veterinary medicine to address the efficacy of these drugs.

SUPPORTIVE THERAPIES

The goals of supportive therapy include seizure control and reduction in intracranial pressure, and these therapeutics are often instituted regardless of whether or not definitive therapies are undertaken. When used in combination with definitive therapy such as surgery or radiation, these treatments aid in reducing the patients' clinical signs in the short term while waiting for definitive treatments to take effect. Supportive therapies can be used as the sole means of treatment, but owners should be made aware that the patient's prognosis is poor; these therapies treat only the symptoms of the intracranial tumor and do not affect the tumor itself. The use of supportive therapies as the sole means of therapy is short-lived because eventually the tumor mass enlarges and exacerbates the patient's clinical signs. However, supportive care can extend a patient's life in the short term and temporarily alleviate clinical signs associated with the intracranial tumor.

Treatment of Intracranial Hypertension

Intracranial hypertension can develop as a result of the presence of a brain tumor or because of its secondary effects such as edema and hemorrhage. Left untreated, intracranial hypertension can cause brain herniation and death. Intravenous fluid support is given to maintain normotension and support blood flow to the brain since cerebral perfusion pressure relies on adequate mean arterial blood pressure. Methylprednisolone sodium succinate (Solu-Medrol, Pfizer) is a glucocorticoid effective at decreasing peritumoral edema (see Table 235-1). Diuretics may also be given to decrease brain edema. Mannitol and hypertonic saline are osmotic diuretics effective at decreasing intracranial pressure (see Table 235-1). It is important to monitor the patient's hydration status when using diuretics since therapy can lead to hypovolemia and hypotension, which can exacerbate cerebral ischemia caused by hypoxia.

Anticonvulsants

Phenobarbital and potassium bromide are the typical first-line anticonvulsants used in veterinary patients

(Table 235-1). Serum phenobarbital concentrations should be measured 2 weeks after initiating maintenance therapy; the therapeutic range is 15 to 45 mcg/ml when used as monotherapy. High levels of phenobarbital may be associated with hepatotoxicity. Increased alkaline phosphatase may be noted on a serum biochemistry profile, although this is associated with hepatic enzyme induction rather than hepatotoxicity. Bone marrow hypoplasia is an uncommon side effect of phenobarbital therapy. Additional side effects include polydipsia and polyuria, polyphagia, sedation, ataxia, and paraparesis. These side effects often resolve within 1 to 2 weeks of initiating therapy. Patients on phenobarbital therapy should have serial serum biochemistry profiles measured, along with regular monitoring of serum phenobarbital concentration to aid in dose adjustments if needed.

Potassium bromide can be used as sole therapy, or it may be added to phenobarbital therapy in refractory cases. Because it takes a long time to reach steady state, patients are usually given a loading dose for 5 days, and a maintenance dosage is given thereafter. Serum concentrations of potassium bromide should be measured in 3 weeks, and the dosage adjusted accordingly. Side effects of potassium bromide are similar to those of phenobarbital. Potassium bromide is not known to cause hepatotoxicity, although it may be associated with pancreatitis. Potassium bromide is not recommended for use in cats since it may be associated with the development of inflammatory pneumonitis. It is important to keep the salt content of the patient's diet consistent while on bromide therapy since increased dietary chloride can reduce the serum levels of bromide and affect seizure control.

The appearance of cluster seizures or status epilepticus is an emergency, and treatment includes the administration of diazepam (Valium, Roche) or midazolam (Versed, Roche). Phenobarbital may be given as a loading dose (see Table 235-1). If these anticonvulsants cannot control the patient's seizures, anesthetics such as pentobarbital, propofol, and gas anesthesia should be considered, realizing that the patient may require ventilatory support.

Corticosteroids

Glucocorticoids may be given to reduce peritumoral edema and decrease CSF production. An antiinflammatory dose of prednisone is recommended (see Table 235-1). This dose can be adjusted based on the patient's response to therapy.

Antihistamines

Meclizine and dimenhydrinate are antihistamines with antiemetic effects, which are useful to alleviate nausea in patients with vestibular disease (see Table 235-1).

Emerging molecular therapies such as immunotherapy, gene therapy, and oncolytic viral therapy have been used with varying success in humans, and these areas may represent direction for future research in brain tumors of veterinary patients.

CHAPTER 236

Diagnosis and Treatment of Atlantoaxial Subluxation

BEVERLY K. STURGES, *Davis, California*

Atlantoaxial (AA) instability with subluxation of C2 relative to C1 is a frequent cause of cervical pain and/or myelopathy in toy and miniature breeds of dogs. On rare occasions large breeds of dogs, as well as cats, may also be affected. Because AA subluxation is a potentially life-threatening problem, it is important to recognize when AA instability *may* be present so that the patient is handled appropriately. This will prevent exacerbation of the clinical signs until a definitive diagnosis is made and appropriate treatment is instituted.

GENERAL CONSIDERATIONS: ANATOMY AND PHYSIOLOGY

The atlas (C1) and axis (C2) form a pivotal joint that allows free movement of the head about the longitudinal axis of the spine. Most of the rotational movement centers around the dens, a bony process projecting from the rostral aspect of the body of the axis, which is held in position relative to the atlas by several ligaments (Figs. 236-1 and 236-2):

- The *apical and alar ligaments* leave the apex of the dens in three sections: the middle one, forming the apical ligament, goes straight forward and attaches to the ventral border of the foramen magnum; the lateral sections, forming the alar ligaments, attach to the skull medial to the occipital condyles.
- The *transverse atlantal ligament* is a strong ligament that crosses over the top of the dens and connects one side of the ventral arch of C1 to the other. It is particularly important to AA joint stability since this ligament holds the dens firmly against the ventral aspect of the atlas.
- The *dorsal AA membrane* is a fibrous extension of the joint capsule running between the arch of the atlas and the spinous process of the axis. It adds support, limiting the amount of dorsoventral movement between C1 and C2.

The atlas articulates rostrally with the occipital condyles of the skull and forms a joint of which the main movements are flexion and extension of the head, the “yes” joint. Caudally the atlas articulates with the axis allowing lateral (and rotational) movement of the head, the “no” joint. Working together, these two joints allow free motion of the head in all directions. The large nuchal ligament, which attaches the spinous process of C2 with

Fig. 236-1 Normal atlantoaxial joint, lateral view. Note the relationships of the ligamentous and bony structures of the AA joint that allow for normal head movement without injury to neural structures.

Fig. 236-2 Normal atlantoaxial joint, ventrodorsal view. The apical and alar ligaments attach the dens to the occipital bones of the skull while the transverse ligament crosses over the top of the dens, keeping it firmly in place against the ventral aspect of the atlas.

those of T1 and T2, functions in suspension of the head by forming a fulcrum at the AA joint (see Fig. 236-1).

PATHOPHYSIOLOGY

Instability of the AA region allows excessive flexion of the joint, which may result in subluxation, traumatic spinal cord injury, and compression. This usually occurs secondary to congenital or developmental abnormalities of the bones or ligaments of the AA joint, traumatic injury to the joint, or a combination of both. In many instances the abnormalities present are associated with the dens and include agenesis/hypoplasia of the dens, dorsal angulation of the dens, and fracture or avulsion of the dens with the axis. Absence or rupture of associated AA ligaments often contributes to the instability caused by congenital anomalies in the region. Traumatic rupture of the AA ligaments without associated anomalies of the AA joint also

Fig. 236-3 Atlantoaxial subluxation, lateral view. Subluxation of the axis (C2) relative to the axis causes traumatic injury and compression of the cranial spinal cord. Associated hemorrhage and edema may extend rostrally to affect brainstem function.

can occur, resulting in instability and spinal cord injury. Dorsal displacement of the cranial portion of the body of the axis into the vertebral canal, acutely or chronically, causes compression, edema, and inflammation of the spinal cord that may extend cranially into the caudal brainstem (Fig. 236-3).

DIAGNOSIS

Clinical Presentation

Malformations of the AA joint occur most frequently in toy and miniature breeds of dogs especially Chihuahuas, Yorkshire terriers, toy and miniature poodles, Pomeranians, Japanese chins, and Maltese. Clinical signs of a C1-C5 myelopathy and/or cervical pain occur and may be acute or chronic at onset and progressive, nonprogressive, or intermittent in nature. Often the signs occur secondary to mild trauma such as jumping off furniture or roughhousing with other dogs. Reportedly signs usually occur within the first year of life; however, at my institution the majority of cases have occurred in dogs older than a year, including middle- to older-age animals. Severity varies from mild to profound cervical pain to tetraparesis, respiratory paralysis, and caudal brainstem signs (e.g., hypoventilation, vestibular syndrome). Traumatic AA instability, with or without an underlying congenital malformation, is usually the cause of AA subluxation in larger-breed dogs (>10 kg).

Occasionally dogs with AA instability may present with a history of seizure-like signs occurring intermittently with or without transient apnea and paresis. Episodes are usually related to a mild traumatic incident and commonly occur with malformations of the dens, specifically agenesis or dorsal angulation of the dens.

Differential diagnoses for dogs with this clinical presentation should include intervertebral disk disease, cervical trauma/spinal fracture, infectious/inflammatory disease (e.g., granulomatous meningoencephalitis [GME], other craniospinal anomalies (e.g., syringomyelia, Chiari-like malformation), and neoplasia (cervical spine or brain). Although the history, signalment, and clinical signs of AA subluxation may be indistinguishable from other common diseases such as GME, disk disease, and Chiari-like malformation/syringomyelia, a diagnosis of instability at the AA joint should be considered significant and treated promptly.

Radiography

Plain cervical radiography usually provides the diagnosis in most instances. Because it is essential that positioning be accurate when evaluating the AA region of the cervical spine, general anesthesia is necessary. It is easy to misdiagnose AA subluxation on imperfectly positioned radiographs or where the beam is not centered on C1-C2. Care must be taken when manipulating an animal suspected of having AA instability during intubation, handling under anesthesia, and radiography since flexion of the animal's neck may result in further spinal cord compression. Placing a Robert Jones–style bandage on the patient before anesthetizing with the head in mild extension provides support and comfort for the animal and serves as a safeguard for keeping the AA joint in extension. Radiographically the body of the axis is displaced dorsally and cranially into the vertebral canal, and the distance between the dorsal arch of the atlas and spinous process of the axis is increased (Fig. 236-4). If lateral views are not diagnostic, slight flexion of the head may be necessary to demonstrate subluxation or instability of the AA joint. Abnormalities of the dens may be seen clearly on oblique lateral views in which the wings of the atlas are not superimposed on the dens and/or ventrodorsal views.

Advanced Imaging

Myelography and/or computed tomography (CT) may be required to confirm that subluxation is present, to further delineate regional problems when multiple congenital anomalies are present, and/or to rule out other differential diagnoses in the same region of localization (e.g., disk disease). Lumbar puncture should be done since cisternal puncture for cerebrospinal fluid (CSF) sampling or myelography is not recommended in dogs with AA subluxation on the differential list. In most cases plain radiography with or without myelography or CT-myelography is sufficient to diagnose AA instability/subluxation.

Magnetic resonance imaging (MRI) may be very useful in the diagnosis of AA subluxation, especially in patients with clinical signs of brain or brainstem disease, as well as cervical pain and myelopathy. The extent of the parenchymal injury to the cervical cord or caudal brainstem is best visualized on MRI. Typically a region of hyperintensity on T2W images is visible in the cranial cervical spinal cord, caudal brainstem, or both locations on MRI. In addition, MRI is useful for ruling out the presence of concurrent diseases with clinical signs localizing to the same region and for identifying underlying disease that may influence long-term prognosis. For example, cavalier King Charles spaniels with signs of cervical pain and myelopathy should be evaluated for the presence of Chiari-like malformation and syringomyelia as well as AA instability. Collection of CSF is recommended in cases in which the diagnosis is not straightforward on imaging, especially in breeds of dogs typically prone to inflammatory disease (e.g., GME) of the brain.

TREATMENT

Patients with cervical pain only or minimal neurologic deficits may respond well to splinting of the head and neck in mild extension and strict cage rest for at least 6 weeks. However, clinical signs often recur once normal activity resumes. Surgical decompression and stabilization is indicated in cases with moderate-to-severe neurologic deficits or intense pain or those that are unresponsive to nonsurgical treatment. Surgery is also recommended when angulation of the dens results in spinal cord injury. Animals less than 6 months of age are best treated conservatively, if possible, to allow for more complete mineralization of bone and closure of vertebral physes before attempting surgical stabilization. Certainly conservative treatment should be attempted in situations in which financial constraints do not allow surgical repair to be done.

Fig. 236-4 **A**, Plain lateral radiograph of a 3-year-old Miniature Poodle with atlantoaxial subluxation. With the head in a neutral position, there is increased space between the arch of C1 and the spinous process of C2, and the cranial aspect of C2 is luxated into the vertebral canal. This dog had several congenital abnormalities, including agenesis of the dens, an associated lack of normal atlantoaxial ligaments and block vertebrae from C2 to C4. **B**, Lateral myelogram of the same dog. The head is now positioned in extension in an effort to relieve compression on the spinal cord. Usually this will allow C1-2 to assume a more normal relationship (thus confirming atlantoaxial instability is present). Due to the chronicity of the problem in this dog and associated formation of fibrous tissue, external reduction of the subluxation was minimal.

Nonsurgical Treatment

Cage confinement, immobilization of the AA region with or without nonsteroidal antiinflammatory drugs (NSAIDs), often results in clinical improvement. Splinting allows for formation of fibrous tissues and healing of ligamentous structures to re-stabilize the AA joint. Ideally it should extend from the mandible to the sternum, incorporating the head in mild extension in an attempt to immobilize the AA joint as much as possible. Casting materials, thermoplastic, or malleable metals may be used to form the splint, which should then be well padded before applying to the patient. Some patients do not tolerate this degree of immobilization well. Toy breeds, especially immature animals, may even experience difficulties eating, walking, and supporting the cranial half of the body. In lieu of this type of splinting, a shorter, Robert Jones–style bandage may be used that incorporates the head (including the caudal aspect of the mandible) down to the caudal cervical region. This is generally tolerable to the patient, keeps the head in mild extension, is easily supported, and appears to be effective, especially in very small dogs (Fig. 236-5). Splints and bandages of any kind should be checked regularly for any signs of complication, including otitis, facial, and corneal excoriations and dermatitis. Bandages are typically left on for a period of 4 to 8 weeks and then removed. The animal is allowed a gradual return to normal activity. If clinical signs of AA instability return, nonsurgical treatment may be reinstituted; however, surgical repair is strongly recommended at this point. Clients often become distraught with repeated episodes of pain/myelopathy and are usually amenable to more definitive treatment with surgery after the first episode.

Fig. 236-5 Supportive bandage for atlantoaxial instability. This Robert Jones–style bandage is useful for providing support to the atlantoaxial joint and maintaining the head in mild extension, thus protecting the spinal cord from further injury. The bandage extends from mid-mandible to the level of C6 and should be loose enough to be comfortable and not cause compression of the jugular veins.

Surgical Treatment

Surgery is indicated for most dogs and cats with clinical signs of AA subluxation. Stabilization of the joint usually results in immediate relief of pain and improved neurologic status, even in the most severely affected animals. Many methods of repair have been described in the veterinary literature. In most circumstances dorsal repairs have largely been replaced by ventral fusion techniques. Stabilization of the AA joint reduces the lateral and rotational mobility of the patient's head, although this is usually well tolerated physically by the animal. The “domino” effect, which is frequently of concern with fusion of vertebrae in the caudal cervical spine, does not appear to be a problem at C1–2.

Ventral Surgical Approach and Technique

Ventral fixation of the AA joint is preferred since these techniques provide direct access to the AA joint. This allows the surgeon to reduce the subluxation and decompress the spinal cord, perform an odontectomy if indicated, and promote arthrodesis between C1 and C2 by removing the articular cartilage and placing a bone graft. However, ventral approaches are technically difficult for many reasons, and complications may occur as a result of:

- Bones that are usually very small, often malformed, and easily fractured during reduction and implant placement.
- Vertebral movement and/or incorrect positioning of implant during placement, causing further injury to the spinal cord and possible paralysis, ventilatory failure, or death.
- Trauma to vital soft tissue structures in the area (e.g., vagosympathetic trunk, carotid artery, trachea, brainstem).

Many ventral techniques for surgical management of AA instability in dogs have been reported (Sharp, 2005; Platt, Chambers, and Cross, 2004; Sanders et al., 2004; Schulz, Waldron, and Fahie, 1997; McCarthy, Lewis, and Hosgood, 1995). In each of these the patient is positioned in dorsal recumbency with the neck in extension, similar to positioning for ventral slot procedures. Usually one or more of a combination of pins, screws, and bone cement is used to immobilize the joint, whereas bony fusion at the site is promoted by the placement of a bone graft into the AA joint (Fig. 236-6). Postoperative care is usually minimal, with pain medications needed for the first 24 to 36 hours and NSAIDs used to treat associated inflammation as needed. Improvement in the neurologic status and the pain score of the patient is usually seen immediately following surgery. Restricted activity or cage confinement is recommended for the first 4 to 6 weeks.

Dorsal Surgical Approach and Wiring Technique

Dorsal repairs of the AA joint were the earliest techniques described for immobilization (McCarthy et al., 1995). However, since fusion of the joint is not achieved, these should be considered palliative procedures only and are not recommended as the first choice for treatment of AA subluxation. The dorsal wiring/suturing technique is the most common (dorsal) method still in use. The

Fig. 236-6 Ventral surgical repair technique of the atlantoaxial joint, ventrodorsal view. In addition to the positive-profile threaded transarticular pins illustrated here, a cancellous bone graft is placed intraarticularly to promote arthrodesis. Larger dogs may require additional pins/screws be placed into C1 and C2 to add more stability until bony fusion occurs.

approach is easy technically, but correct placement of the wire/suture may be difficult and associated with several potential complications:

- Further injury to the spinal cord may occur during wire placement.
- Disruption of internal vertebral venous sinus may cause significant hemorrhage and/or hematoma formation within the vertebral canal, exacerbating clinical signs.
- Wire/suture may cut through the lamina of C1, especially in the soft bones of immature dogs.

Postoperative placement of a splint or bandage is recommended for 6 weeks to keep the AA joint as immobilized as possible until scar tissue forms.

PROGNOSIS

The prognosis for animals with AA subluxation varies, depending on the chronicity and severity of the spinal cord injury that occurs. Generally speaking, long-term outcome is very good to excellent for animals treated surgically that have clinical signs of pain with or without mild to moderate neurologic deficits. Animals presenting

with severe tetraparesis/tetraplegia and respiratory distress, especially with a chronic history, have a guarded prognosis for good recovery of neurologic function (Beaver et al., 2000; Knipe et al., 2002). Reported success rates of ventral surgical techniques vary from 79% to 92% for a good-to-excellent outcome (Schulz, Waldron, and Fahie, 1997; Beaver et al., 2000; Sanders et al., 2004; Platt, Chambers, and Cross, 2004; Knipe et al., 2002), with no one method overtly superior with respect to long-term survival. The experience and comfort level of the surgeon in performing surgery in the AA region is likely one of most important influences on the overall outcome of patients with atlantoaxial disease.

A study that followed the long-term outcome of dogs treated nonsurgically found that dogs with an acute onset of clinical signs and no prior history of signs of AA instability had a good outcome about 60% of the time, regardless of the severity of the presenting neurologic status (Havig et al., 2005). However, dogs treated nonsurgically that had clinical signs for longer than 30 days were significantly more likely to have a poor final outcome.

It is emphasized that *the presence of pain perception is of little prognostic value in animals with AA subluxation* because severity of compression required for loss of deep pain at this level of the spinal cord usually causes respiratory paralysis and death.

Treatment of Canine Cervical Spondylomyelopathy: A Critical Review

ANNIE V. CHEN, *Pullman, Washington*
RODNEY S. BAGLEY, *Pullman, Washington*

Cervical spondylomyelopathy (CSM) is a neurologic condition that affects large-breed dogs, particularly Great Danes and Doberman pinschers. Numerous medical and surgical treatments have been attempted; however, the most appropriate treatment still remains controversial. Reasons for such controversy arise from the complexity of this disease process and the incomplete understanding of its pathogenesis. Opinions vary as to the etiology, diagnosis, and treatment of this disease; consequently it has acquired several names. Diagnostic descriptors include wobbler syndrome, cervical spondylopathy, cervical vertebral instability, cervical vertebral malformation-malarticulation, and cervical spondylolisthesis.

ETIOLOGY AND PATHOPHYSIOLOGY

The etiology of CSM is likely multifactorial and has been speculated to be caused by nutritional, traumatic, or genetic factors. The fact that large-breed dogs are most commonly affected heightens the suspicion that breeds with long necks and heavy heads create increased physical stress on the cervical spine and therefore predispose these breeds to this disease. In addition, rapid growth in large-breed dogs can adversely affect the development of the cervical spine, contributing to vertebral canal stenosis, vertebral body malformation, vertebral subluxation, and vertebral instability. Pedigrees have also been reviewed in both Great Danes and Doberman pinschers that suggest a genetic contribution to this disease. Regardless of the etiology, this disease becomes clinically significant when it leads to compression of the spinal cord and/or instability of the spine.

There are two major types of compressive lesions encountered with CSM: osseous and primary soft-tissue abnormalities. Osseous compression (bony stenosis) is typically seen in young, immature dogs, particularly large or giant breeds such as Great Danes. These dogs may have congenital malformations of the cervical vertebrae (articular facet, pedicle, vertebral arches) that then lead to a narrowed vertebral canal. Multiple vertebral sites are usually involved, although focal osseous malformation is also possible. The degree of osseous compression can change with flexion or extension of the neck. These abnormalities may result in either dynamic or static compressive lesions.

Soft-tissue compression can be dorsal, lateral, or ventral but is most often dorsal or lateral in these young, large- or giant-breed dogs. Types of dorsolateral soft-tissue compression include ligamentum flavum (interarcuate ligament) hypertrophy, joint capsule proliferation, and synovial cyst formation.

Ventral soft-tissue compression typically is related to intervertebral disk degeneration with protrusion of the annulus fibrosus. This is most commonly seen in older adult dogs, particularly Doberman pinschers. Subluxation or “tipping” of the cranial aspect of the vertebral body dorsally into the spinal canal can also result secondary to the degenerative disk. It is important to recognize that not all radiographically apparent vertebral “tipping” leads to spinal cord compression and clinical deficits. Doberman pinschers are most commonly affected at the C6-7 intervertebral disk space and to a lesser extent at C5-6 and C4-5. This type of compression can also be dynamic with alleviation of the ventral spinal cord compression on flexion of the neck.

MEDICAL TREATMENT AND PROGNOSIS

Traditionally medical management of CSM has consisted of cage confinement, restricted activity, external support braces or bandages, pain medication, muscle relaxants, and/or antiinflammatory drugs such as corticosteroids or nonsteroidal antiinflammatory drugs. Although each of these treatments have been perpetuated in the veterinary literature, the available evidence to support the success of these treatments is mostly anecdotal.

Results of medical management of CSM have varied in the literature. Interpretation of reported results is complicated by the fact that documentation of the natural course of this disease in a large group of similarly affected dogs has not been performed. Since this overall pattern of disease with an associated prognosis is not established, assessment of treatment options becomes difficult without a well-defined, prospective, randomized study. Therefore reported outcomes of medical management are difficult to interpret. It is also important to realize that cases treated successfully in private practice with medical therapy may not form part of the literature. Therefore it is possible that the success rate with medical management is higher than reported.

Denny, Gibbs, and Gaskell (1977) retrospectively reviewed 25 large-breed dogs, primarily Great Danes, with CSM that had restricted exercise as the treatment. Nineteen dogs (75%) were euthanized for their neurologic disease, one dog recovered after a few months and remained normal for 3 years, one dog slightly improved at 1 year follow-up, one dog showed no change at 1 year follow-up, and three dogs were lost to follow-up. Duration to euthanasia ranged from 2 weeks to 5 years with a median of 4 months.

Overall, medical treatment may be effective for dogs with less severe clinical signs of CSM, although this has not been evaluated objectively. Typically surgery is performed in dogs that present with severe neurologic deficits, are unresponsive to medical management, or show signs of progressive disease.

SURGICAL TREATMENT AND PROGNOSIS

Surgical treatment of CSM has been used since the 1970s. Despite various case studies describing and evaluating different surgical techniques, there is no strong evidence (double-blinded, placebo-controlled, randomized, multicenter study) that shows one surgical procedure to be superior over the others or in some instances better than nonsurgical management. To further complicate the assessment of treatment responses, identification of the unique patient factors that may make one therapy more or less effective for an individual patient is currently unestablished. Therefore information reported historically about surgical treatment of this disease is primarily descriptive.

One of the earliest published reports on surgical treatment for CSM in Doberman pinschers was described by Mason in 1977. Cervical spondylomyelopathy was diagnosed based on clinical signs and radiographic changes without or in some instances with myelography. The results of the radiographic changes in relationship to the age of the dog suggested that intervertebral instability was the primary lesion and that degenerative changes to the disk and proliferative changes to the vertebrae were secondary to excessive mobility and abnormal forces. Twenty-five Doberman pinschers had fenestration of the intervertebral disks with a Bard Parker No. 11 blade and the removal of the nucleus with a small spatula from C2-T1. The proposed theory behind this procedure was that, with the removal of the nucleus, the intervertebral disk space would collapse and form fibrosis, which would increase the stability of the cervical spine. Treatment was considered effective if alleviation of clinical signs were noted. The author concluded that treatment by fenestration was effective in cases that showed only vertebral instability (younger dogs) and much less effective in older dogs (>2.5 years old) with associated degenerative changes. How the author determined vertebral instability was not clearly defined in this report.

In 1977 Denny, Gibbs, and Gaskell published data from 10 large-breed dogs with CSM that were treated surgically. Clinical diagnosis was supported by radiographic demonstration of cervical vertebral abnormality. The principal radiologic sign of intervertebral instability was dorsal displacement of the cranial margin of a vertebral body

with respect to the caudal margin of the vertebra cranial to it. The affected vertebrae were stabilized by screw fixation of the vertebral bodies across the intervertebral disk space in eight dogs (Gage and Horelein, 1973), by plate fixation of the vertebral bodies in one dog, and by screw fixation of the laminar articular facets in one dog (Parker et al., 1973). Bone grafts were used in nine dogs to help promote early spinal fusion. Dorsal laminectomy was carried out in conjunction with stabilization in one dog. Six dogs (60%) improved at various follow-up times, one had no improvement, and three showed a transient improvement followed by deterioration and were euthanized.

Ventral decompression was evaluated as a treatment for cervical disk protrusion in large- and giant-breed dogs by Chambers and colleagues (1982). Twelve dogs, the majority of them Doberman pinschers (9/12), diagnosed with caudal cervical disk herniation (soft-tissue compression) with radiographs and myelograms underwent ventral decompression with the removal of the dorsal annulus, dorsal longitudinal ligament, and herniated disk material (full-thickness ventral slot) (Gilpin, 1976). After a follow-up period averaging 16 months after surgery, six dogs (50%) were neurologically normal, and six dogs (50%) were functional pets with minor residual proprioceptive deficits. These authors concluded that ventral decompression alone is a satisfactory treatment for dogs with caudal cervical disk herniation without coincidental instability. It is important to note that dogs with radiographic evidence of vertebral instability (vertebral subluxation, misshapen vertebrae, spinal canal stenosis, spondylosis deformans, or proliferation of the articular facets) were excluded from this study.

Fenestration for treatment of degenerative disk disease in the caudal cervical region of large-breed dogs was evaluated by Lincoln and Pettit in 1985. Fifteen of the seventeen dogs were Doberman pinschers. Disk disease was diagnosed based on survey radiographs and myelograms. Fenestration of multiple caudal cervical disks was performed using a No. 11 scalpel blade, and disk material was removed using curettes and rongeurs. Four dogs (24%) had complete remission of clinical signs; seven dogs (41%) showed persistence or return of pain, ataxia, or dysmetria but without further progression; and six dogs (35%) had deterioration of clinical signs after surgery. In general, dogs with spinal cord compression that was not relieved by flexion or traction of the neck on the stress myelograms and those with spinal canals of smaller diameter became progressively worse after fenestration. The authors concluded that disk fenestration may not resolve a problem caused by a compressive degenerative disk since the dorsal part of the annulus fibrosus remains and may even be pushed into the spinal canal after fenestration. This was confirmed on two postmortem examinations.

In 1986 Chambers, Oliver, and Björling published a retrospective study on 27 CSM-affected Doberman pinschers that underwent full-thickness ventral slot for decompression of the spinal cord. Myelograms were used to identify the site(s) of compression. The types of compression present were not clarified by the authors. There were no deaths during surgery or in the immediate postoperative period. Within a few months of surgery 9 of the 27 dogs

(33%) either died or were euthanized because of postoperative complications or persistent or progressive neurologic deficits. Six dogs were necropsied, and residual spinal cord compression was found at a previous surgical site. The remaining dogs (67%) were either normal or had minimal residual deficits. The follow-up period varied from 6 months to 4 years. The authors concluded that this surgical technique was very challenging to perform and had a high percentage of failures.

A distracted cervical spinal fusion technique using an autogenous bone graft from the iliac crest, 4-mm cancellous bone screws, and polymethyl methacrylate (PMMA) was described by Ellison, Seim, and Clemmons in 1988. Ten CSM-affected Doberman pinschers had evidence of dynamic soft-tissue spinal cord compression on the stress myelograms. Dogs with disk herniation that did not flatten with traction views were not candidates for this surgery. A partial-thickness ventral slot was performed up to the level of the dorsal portion of the annulus fibrosus and the dorsal longitudinal ligament. Gentle traction was placed on the neck, and the proper-size bone graft was placed in the slot using a pin tap. Partially threaded 4-mm -diameter cancellous bone screws were initiated on midline and angled 30 degrees away from perpendicular. Two diverging screws were placed in each of the adjacent vertebrae, and PMMA was used to cover the ventral aspect of the screws. After surgery, eight dogs (80%) had either improved neurologic status or elimination of cervical pain. Implant loosening was seen in three dogs, and two of them were euthanized because of lack of neurologic improvement. Evidence of bony cervical fusion was seen on radiographs during a 9- to 24-week period in six of the eight surviving dogs. The authors concluded that this was a valid surgical procedure for treatment of CSM in dogs when the compressive lesion is limited to one cervical intervertebral disk space.

In 1989 Bruecker, Seim, and Withrow retrospectively evaluated three surgical methods for the treatment of CSM caused by chronic degenerative disk disease in 64 dogs, of which 48 were Doberman pinschers. Twenty dogs had full-thickness ventral slot exposing the spinal cord. Seven dogs had partial-thickness ventral slot, linear traction, bone graft, and interbody screw placement. Thirty-seven dogs had partial-thickness ventral slot, linear traction, bone graft, and placement of the plastic plate on the ventral aspect of the vertebral bodies. Interbody screw stabilization was ineffective because of an unacceptably high rate of implant failure. Full-thickness ventral slot or plastic plate stabilization was an effective treatment for CSM patients with mild-to-moderate neurologic deficits. Dogs with severe neurologic deficits (weakly ambulatory to nonambulatory tetraparesis) had variable success rates and prolonged recovery periods. Follow-up time ranged from 3 to 50 months with a mean of 20 months. A second compressive lesion developing at an adjacent intervertebral space (known as domino lesion) was seen with all three surgical methods.

In 1990 McKee and colleagues prospectively evaluated a vertebral distraction-fusion technique using a transvertebral screw and two interbody washers. Seventeen Doberman pinschers and three Great Danes were included in this study. A diagnosis of CSM was made based on stress

myelography. All dogs had evidence of spinal cord compression at C6-7, and six dogs also had spinal cord compression at C5-6. Spinal cord compression was associated with the dorsal protrusion of the annulus fibrosus. Traction on the cervical spine reduced the degree of compression in 23 of the 26 protrusions. Double washers were used at 24 sites, and a single washer was used at two sites of cord compression because of inability to distract the affected disk spaces sufficiently. Fifteen dogs were radiographed 6 months following surgery; they all showed evidence of vertebral end-plate resorption and new bone production ventrally around the implants. Ten dogs radiographed 18 months following surgery showed bone production around the implants, which the authors concluded to be vertebral bony fusion. Seventeen dogs (85%) improved following surgery, one died in the early postoperative period as a result of a gastric dilation and volvulus, and two were destroyed because of fracture of the ventral spinous process of C6.

A modified distraction-stabilization technique using an interbody PMMA plug in dogs with CSM was described by Dixon, Tomlinson, and Kraus in 1996. Eighteen Doberman pinschers, two German shepherds, one Great Dane, and one rottweiler underwent this surgical procedure. Diagnosis of CSM was made on the basis of history, clinical signs, and myelographic confirmation of a dynamic compressive cervical lesion. The predominant component of the compressive lesion was ventral to the cord as a result of a protruded dorsal annulus. A partial-thickness ventral slot was performed, and approximately 3 to 5 mm of dorsal annulus and bony end plates was left intact. Linear distraction was applied using blunted Gelpi retractors and laminectomy spreaders. PMMA anchor holes were drilled into the vertebral end plates using a pneumatic drill. PMMA was placed into the prepared disk space while traction was maintained. After PMMA hardened, the traction device was removed, and cancellous bone graft was placed along the ventral aspect of the exposed vertebral bodies. This technique was used for two adjacent disk spaces in nine dogs and in a single disk space in thirteen dogs. Nineteen dogs (86%) were considered successes long term, with 50% of the dogs returning to normal neurologic function. Two dogs (9%) were considered failures. The two failures were both nonambulatory before surgery. Follow-up time ranged from 3 to 60 months with a median of 18 months. Criteria for success and failure were defined by the authors. Major complications with this procedure were not observed. This procedure was not recommended in dogs with static ventral spinal cord compressions.

In 1998 Rusbridge and colleagues compared two surgical techniques for the management of CSM in Doberman pinschers: full-thickness ventral slot (Swaim, 1973) versus vertebral distraction and stabilization using the screw and washer technique (McKee et al., 1990). Twenty-eight Doberman pinschers were retrospectively included in the study. Immediately following the ventral slot procedure, 6 of 14 dogs (43%) deteriorated neurologically. This neurologic deterioration was suspected to be caused by iatrogenic injury during surgery or reperfusion injury after decompression of the spinal cord. At 6 months after surgery, 13 of 14 of the ventral slot dogs and 12 of 14 of the screw

and washer dogs had satisfactory outcomes. At 1 year after surgery the recurrence rate was zero for the ventral slot procedure and 5 of 14 (36%) for the screw and washer technique. At 2 years after surgery, 4 of 14 (29%) of the ventral slot dogs had deteriorated compared to 7 of 14 (50%) of the screw and washer dogs. When clarified, the cause of the deterioration was the result of either a domino disk lesion or dorsal displacement of the screw and washer secondary to vertebral end-plate collapse. The authors concluded that both procedures have satisfactory short-term results. The ventral slot procedure was more time consuming and had more immediate postoperative deterioration. However, recurrence of clinical signs more likely was seen after the screw and washer technique.

In 1998 Queen and colleagues questioned the need for distraction in dogs with disk-associated CSM. Because of the increased risk of vertebral collapse secondary to the distraction reported in the literature, the authors described a technique of vertebral body fusion without distraction, using two position screws (for short-term stability) and a partial-thickness ventral slot filled with cancellous bone graft (to promote fusion for long-term stability). Seventeen Doberman pinchers were diagnosed with CSM based on radiography and myelography. A partial-thickness ventral slot was performed at C6-7, two cortical bone screws were placed parallel to each other across the disk space, and cancellous bone graft taken from the proximal humerus was placed into and around the slot. Follow-up interval ranged from 3 weeks to 35 months. One dog was lost to follow-up. Thirteen of 16 cases (81%) neurologically improved within the first 3 months after surgery. Three cases (19%) were euthanized after surgery because of neurologic deterioration as a result of incorrect screw placement of one of the screws. The authors hypothesized that increased vertebral stability is the major contributor to long-term clinical improvement by allowing atrophy of the intervertebral soft tissues and/or by eliminating any dynamic component of this disease.

The intervertebral metal washer technique for the management of CSM-associated intervertebral disk protrusions was reevaluated by McKee, Butterworth, and Scott in 1999. Seventy-eight cases were reviewed retrospectively. Myelography demonstrated traction-responsive cervical spinal cord compression. Fifty lesions were evaluated myelographically on immediate postoperative radiographs. Of these, 32 spinal cord compressions had been eliminated, and 18 had been reduced. Within 6 months of surgery, euthanasia was performed in nine dogs (12%) because of neurologic deterioration, and 15 dogs (19%) had varying degrees of neck pain. Vertebral end-plate fracture was considered a key factor in these 24 cases. Sixty-five of the 78 cases were studied long term with a median follow-up time of 32 months. Sixty-three of the 65 cases (97%) improved after surgery. However, neurologic deterioration eventually occurred in 17 of the 65 cases (26%). Myelographic evaluation in 8 of the 17 cases revealed additional disk protrusions with no evidence of cord compression at previous surgery sites. These additional disk protrusions were suspected to be domino lesions. The authors concluded that, although the intervertebral washer technique had low perioperative morbidity and was effective in eliminating or reducing spinal

cord compression, the unpredictable nature of vertebral end-plate fracture remained a significant concern.

In 2001 Lipsitz and colleagues evaluated the continuous dorsal laminectomy technique in 14 large-breed dogs with CSM. All dogs were ambulatory at the time of presentation. Spinal cord compression as a result of the hypertrophy of the interarcuate ligament, hypertrophy and soft-tissue proliferation associated with the articular processes, and synovial cysts were identified using magnetic resonance imaging. These changes were all confirmed at surgery. The follow-up period ranged from 2 months to 2 years. Eleven dogs (79%) had an excellent outcome based on resolution of clinical signs as defined by recheck examination and owner telephone consultation. Three dogs had a poor outcome: one died after surgery from cardiac arrhythmias, one deteriorated neurologically after an epileptic event, and one sustained iatrogenic spinal cord injury during surgery but was improving 2 months later. The authors concluded that a dorsal laminectomy can be performed at multiple levels in CSM-affected dogs with lesions at multiple sites.

A retrospective study was performed by De Risio et al. in 2002 to evaluate the postoperative morbidity and long-term outcome of CSM-affected dogs after dorsal laminectomy. Twenty dogs were included in this study; seven were Great Danes, and six were Doberman pinchers. Myelography and/or computed tomography was used for the diagnosis of CSM. The dynamic nature of the disease was not evaluated in all dogs. Sites of spinal cord compression varied from 1 to 4 and were osseous and/or soft tissue in nature. All dogs had dorsal laminectomy at the site(s) of spinal cord compression. Neurologic status worsened in fourteen dogs (70%) 2 days after surgery but improved in all but one dog over long-term follow-up of 7 months to 9 years. Nineteen dogs (95%) were clinically improved according to owners and referring veterinarians after surgery. Mean time to optimal recovery was 3.6 months. However, recurrence of clinical signs was seen in six dogs (30%). The authors concluded that, although most dogs worsen neurologically in the immediate postoperative period after a dorsal laminectomy, this deterioration was usually transient, and the average time to reach optimal neurologic status was similar to the recovery time for other cervical spinal cord surgery.

OBSERVATIONS AND CONCLUSIONS

Although the literature contributes to our knowledge of CSM in dogs, there are limitations to these studies. When reviewing the literature critically, variable details on the rate of onset, duration of neurologic signs, severity of neurologic dysfunction, diagnostic work-up, and clinical follow-up make comparison of these surgical techniques difficult. For example, different patient inclusion criteria were used between studies. Although all dogs had some form of CSM, certain studies only evaluated specific breeds of dogs, assessed only traction-responsive (dynamic) lesions, excluded dogs with osseous lesions, or never made a distinction between dynamic and static lesions. The majority of the studies focused primarily on traction-responsive, disk-associated soft-tissue compressions. There were fewer studies on the surgical treatment of the osseous form of CSM. This exclusion ultimately

creates a bias and makes interpretation of the results challenging. In addition, the definition of long-term follow-up differed among studies. Even within a study itself, the follow-up times varied between weeks and years, making the reported long-term outcome and recurrence rate somewhat unreliable. Follow-up methods also were variable in that some were performed by veterinarians whereas others were based on client surveys or telephone interviews. Finally, the surgical approach and technique can differ significantly among surgeons. For example, a ventral slot can be made at different widths and lengths and can be of full or partial thickness. Distraction also can be variable since the optimal degree of distraction is unknown. Therefore, depending on what was actually performed and the surgical skills of the surgeon, the outcomes and potential risks can vary tremendously, even with a specific procedure.

In general, surgical techniques for CSM have focused on decompression, stabilization, or both. Decompression can be either direct or indirect. Direct decompression typically is done through a ventral slot or dorsal laminectomy. Indirect decompression uses bone plates, pins, screws, or PMMA to maintain vertebral distraction. Using surgical implants can also eliminate vertebral instability at least in the short term while the vertebrae fuse. Additional procedures such as disk fenestration and bone grafting have also been described. Bone grafts often are used in conjunction with distraction techniques for the purpose of promoting bony fusion. All of these techniques can be useful, but there is no single surgical technique that can be applied effectively to all forms of CSM.

Therefore the *choice of surgical technique depends on a number of factors*: the location of the compression (ventral, lateral or dorsal) to the spinal cord, the type of compression (soft versus osseous), the number of disk spaces involved (single versus multiple sites), and whether or not the lesion is traction responsive (dynamic versus static). In general, decompression of a dorsal or lateral, osseous or soft-tissue compression (interarcuate hypertrophy, joint capsule proliferation, extradural synovial cyst) requires a dorsal laminectomy. Some surgeons may also advocate stabilization, hoping for regression of osseous and soft-tissue proliferation over time. The ventral, soft-tissue, traction-nonresponsive (static) lesion requires direct decompression through a ventral slot. Surgical treatment for the ventral, soft-tissue, traction-responsive (dynamic) lesion is most controversial. Both direct and indirect decompressions have been described. Whether or not stabilization of the affected vertebrae is necessary still remains in question.

Initially instability was proposed in the pathogenesis of CSM because of malalignment of the caudal cervical vertebrae on radiographs during flexion and extension. This idea has been perpetuated over time and has not been evaluated objectively. Although there are case studies that advocate the importance of stabilization for the treatment of CSM, there are also studies that have had comparable postoperative results without stabilization. Some surgeons argue that stabilization should be performed in all forms of CSM (dynamic and static) because increased vertebral stability can result in intervertebral disk atrophy and osseous regression, which can lead to

eventual absence of spinal cord compression. However, other surgeons argue against stabilization because of the reported implant failure or domino lesions. Whether or not instability can be proven in CSM-affected dogs becomes the important question. It is possible that some CSM-affected dogs have underlying instability whereas others don't, which then makes this distinction important before surgery. Also, some clinicians propose that CSM-affected dogs may have instability during the early stages of disease but can actually restabilize as the intervertebral disk degenerates further. Dynamic imaging studies such as stress myelography or magnetic resonance imaging may help identify instability, but microinstability is not detectable with such modalities. The clinician is often left with deciding whether or not stabilization is appropriate based on an educated guess as to the degree of spinal instability. Typically a significant dynamic lesion suggests that surgical therapy should involve stabilization of the vertebrae. The goal of stabilization may be to treat instability in the short term, but long-term stability requires bony fusion, or the implants can fail. Whether spinal fusion ever occurs and to what extent in the stabilized patient remains unclear. Bony proliferation on radiographic follow-up may suggest bony fusion and stabilization, but no concurrent histopathologic and biomechanical studies have proven this to be true.

Risks of the surgical procedure should also be taken into consideration when choosing the appropriate surgical technique. Dorsal laminectomy and ventral slot have been associated with a higher level of postoperative morbidity in some studies. This morbidity may be due to the result of iatrogenic injury to the spinal cord, an acute increase in vertebral instability caused by the removal of surrounding stabilizing structures, or hypothesized reperfusion injury to the spinal cord after decompression. Reported morbidity is variable and most likely the result of differences in surgical approach and technique among surgeons. Indirect decompression (distraction) can also lead to catastrophic consequences. Distraction is often lost over time because of bone resorption on either side of implant. This can be clinically inconsequential, but this implant/end-plate failure can result in significant vertebral instability, vertebral collapse, and end-plate fracture in some dogs.

In addition, *recurrence rates* have been documented for most surgical techniques in the literature. In general, reported recurrence rate after CSM surgery in the dog is between 10% and 40%. Recurrence of clinical signs can be caused by progression of previously identified disease or secondary to domino lesions. It has been suggested that intervertebral immobilization promoted by distraction/stabilization techniques may predispose degeneration of the neighboring intervertebral disk spaces, resulting in domino lesions. It is also possible that the degeneration of the neighboring disks is part of the natural course of CSM and is unrelated to the immobilization of the spine. Overall, recurrence rates need to be interpreted carefully because of the differences in follow-up times, follow-up methods, and surgical skills of the surgeons.

The lack of knowledge of the natural history of canine cervical spondylomyelopathy makes treatment recommendation for this disease difficult. It is known anecdotally that some dogs can respond to medical management

alone whereas others require surgical intervention or both. However, the dilemma in veterinary medicine centers around the lack of solid evidence in our literature. With the reported variation across published studies, interpretation of the results is challenging. For clinicians to better understand the natural history of CSM and make appropriate recommendations for treatment will require double-blinded, placebo-controlled, randomized, large sample-size studies. Until that time, definitive recommendations cannot be made, and the clinician should try to appreciate the complex nature of this disorder so to best counsel the client.

Treatment of Degenerative Lumbosacral Stenosis

DANIEL G. HICKS, *Pullman, Washington*
RODNEY S. BAGLEY, *Pullman, Washington*

A degenerative condition of the lumbosacral (LS) joint causing radiculopathy is encountered regularly in dogs. Despite the common occurrence of this disorder, details of pathophysiology, diagnosis, and appropriate treatment are still debated. In addition, most reports detailing diagnosis and treatment are retrospective in nature, without a standard of diagnosis. Because of the complex pathophysiology involved, grouping dogs into a single disease that involves degeneration of the LS articulation may not be reasonable. These and other factors contribute to the debate about which therapy is most effective.

The LS region is comprised of the vertebral bodies of the caudal lumbar and sacral spine, facet joints and synovial joint capsules, the intervertebral disk elements of the L7-S1 disk, ligamentum flavum, intervertebral foramina, paraspinal musculature, other associated supporting structures, and terminal spinal nerves. Additional musculoskeletal elements of the pelvic limbs may biomechanically influence events in the LS region. These include the LS articulation, pelvis, sacroiliac, and coxofemoral structures. Concentrating purely on the neural elements, any abnormality that causes static or dynamic compression of neural elements in this region can lead to radiculopathy. Since one of the most common clinical features of LS disease process is pain, any of the aforementioned anatomic elements may contribute to this clinical sign.

TERMINOLOGY

Before attempting to determine if a treatment is effective, it is paramount that the disease under treatment be identified specifically and its pathophysiology understood. As stated above, multiple pathologic processes may affect the LS region in dogs and cats causing similar clinical signs. Neoplasia, diskospondylitis, fracture/luxations, meningitis, and vascular-based spinal disease could mimic degenerative LS stenosis (DLSS). In the past, these diverse disease processes have been grouped under the same general term of "LS disease" (Berzon and Dueland, 1979; Mayhew et al., 2002). Inappropriate conclusions about diagnosis, treatment, and prognosis of DLSS could be drawn from such reports, when the actual cause of the LS diseases was not established. Furthermore, terms such as *cauda equina syndrome*, *LS disease*, *LS stenosis*, and *degenerative LS stenosis* all have been used to imply a more generic description of clinical signs reflective of an abnormality within the LS region. For this discussion DLSS will be used to describe a

degenerative process of the LS region and exclude other potential etiologies of LS disease. This degeneration may occur spontaneously or may be the result of excessive or repeated "wear and tear" of this region.

PATHOPHYSIOLOGY

Degenerative LS stenosis implies that the spinal nerves coursing through the terminal spinal canal or associated intervertebral foramina are pathologically altered, usually by some form of compression or impingement. The extent of radiculopathy leads to a wide spectrum of clinical manifestation, including pain and nervous system dysfunction. Neural element compression is caused by intervertebral disk degeneration (protrusion of dorsal annulus fibrosus), proliferation of the ligamentum flavum or synovial joint capsule, vertebral joint osteophytosis, intermittent claudication, and LS spondylosis (De Risio et al., 2001; Shulman and Lippincott, 1988; Berzon and Dueland, 1979). Chronic repetitive motion of the LS joint leads to accelerated degeneration in some dogs and cats. In addition, compression of neural elements may be dynamic and influenced by the position of the spine, pelvis, and limbs. Flexed compared to extended radiography and magnetic resonance imaging have demonstrated position-dependent changes in the vertebral conformation and neural element compression (Oliver, Selcer, and Simpson, 1978; Schmid and Lang, 1993; Hicks et al., 2006). Whether LS joint degeneration leads to clinically apparent disease is potentially the result of numerous pathologic variables. Malarticulation, malformation, osteochondrosis dissecans, transitional vertebra, congenital malformation or stenosis, and long-term high motion of this joint complex are usually suspected to be components of this disease process. Breed predispositions may reflect inherent genetic or congenital conformational attributes or represent dogs more commonly selected as working dogs.

Complexities in the pathophysiology of DLSS may result in different clinical manifestations. These clinical features can include LS pain, reduced activity, unwillingness to climb stairs or jump, reluctance to sit, fecal or urinary incontinence, changes in tail carriage, kyphotic posturing, a stiff, stilted, or lame pelvic limb gait, pain on tail manipulation, or pain on direct LS palpation (external or per rectum) (Shulman and Lippincott, 1988; Oliver, Selcer, and Simpson, 1978; Scharf et al., 2004). Paraparesis

or monoparesis also may be present. Spinal reflex abnormalities include decreased withdrawal, decreased anal tone, and decreased bulbocavernosus reflex. The patellar reflex is not reduced but can appear increased (pseudo-hyperreflexic) or normal. Decreased tail tone and muscle atrophy (especially the sciatic nerve-dependent muscles) may also be present. Attention should be given to the symmetry of muscle tone and size (particularly the cranial tibial muscles) between pelvic limbs. Incontinence or perineal hypalgesia may be noted, reflecting pudendal nerve dysfunction. Occasionally self-mutilation is noted, likely resulting from a local paresthesia (Mayhew et al., 2002).

DIAGNOSIS

Diagnosis of DLSS can be challenging considering the various pathophysiologic changes. Moreover, historically-used diagnostic tests were not specific or always accurate. Lacking standardized criteria for diagnosis of DLSS, universal agreement on the diagnosis is difficult and it follows that comparisons of treatments may not be possible.

Magnetic resonance imaging has become the “gold-standard” in evaluating the anatomic components of the central nervous system; however, it may have limitations for diagnosis of DLSS (De Risio, Thomas, and Sharp, 2000; Adams et al., 1995; Karkkainen, Punto, and Tulamo, 1993; Chambers et al., 1997). In addition, the LS joint can be imaged in different positions (extension, neutral, and flexion) to assess changes in neural element compression. Findings consistent with DLSS include degeneration of the L7-S1 intervertebral disk (loss of signal intensity of the nucleus pulposus on T2-weighted images); spinal canal narrowing caused by protrusion of the dorsal annulus fibrosus; extrusion of the nucleus pulposus; hypertrophy of the dorsal longitudinal ligament, interarcuate ligament, and/or synovial joint capsules (facet joints); synovial cysts; osteophytosis of the facet joints; and loss of epidural fat in the LS region (Jones, Banfield, and Ward, 2000; Rossi et al., 2004). It is important to note that abnormal imaging findings may occur in some dogs without obvious associated clinical signs. In the absence of such signs, pathologic imaging alterations in the LS region could lead to over diagnosis of DLSS (DeRisio, Thomas, and Sharp, 2000; Mayhew et al., 2002).

TREATMENT

Historically both medical and surgical options have been used as treatment of DLSS. Current treatment recommendations for this disease often are based on historical precedent, anecdotal communication, and retrospective studies. No standardized, blinded, randomized, and controlled clinical trials have been published regarding treatment of this condition.

Historically dogs with less severe clinical signs or those with contraindications for surgery receive medical treatment alone, resulting in inherent bias in patient selection. Severely affected dogs such as those with fecal or urinary incontinence or marked sensory or motor deficits or those that do not respond to medical management are surgical

candidates, resulting in a similar treatment bias (Chambers, 1989). Multiple surgical techniques have been used to (1) decompress LS neural elements, and/or (2) distract and fuse the LS joint (Auger et al., 2000; Berzon and Dueland, 1979; Schmid and Lang, 1993; Sharp and Wheeler, 2005; Slocum and Devine, 1986). Evidence favoring either of these techniques has not been firmly established.

Dorsal laminectomy, partial discectomy, foraminotomy, and facetectomy have been used for neural element decompression (Chambers, Selcer, and Oliver, 1988; Danielsson and Sjöström, 1999; Lorraine et al., 2003; Tarvin and Prata, 1980). One study of 26 dogs with presumptive DLSS reported clinical improvement in all dogs after dorsal laminectomy and excision of hypertrophied tissue (Chambers, Selcer, and Oliver, 1988). Another retrospective study evaluated 69 dogs after dorsal laminectomy to treat suspected DLSS. Fifty-four of the 69 dogs improved after surgery according to reevaluation either by the veterinary specialists or the referring veterinarian or telephone interviews with the owner (De Risio et al., 2001). An investigation of 26 military working dogs treated with decompressive surgery was also reported. Surgeries were dissimilar and included laminectomy alone or laminectomy in combination with facetectomy, foraminotomy, discectomy, or distraction/fusion. Six of these dogs did not return to function, 9 improved, and 11 returned to normal (Lorraine et al., 2003). Overall, dogs more severely affected neurologically before surgery tended to have a poorer prognosis. A larger study of 131 dogs diagnosed with DLSS based on clinical signs, history, and radiography had a dorsal laminectomy with or without a foraminotomy. Telephone interviews with clients reported that all dogs improved after surgery; 103 reportedly became normal, and 28 were less clinically affected (Danielsson and Sjöström, 1999). Dorsal laminectomy has also been reported as a possible treatment of DLSS in cats (Hurov, 1985).

Distraction and fusion of the LS joint without laminectomy has also reportedly been used to treat dogs with DLSS (Auger et al., 2000; Slocum and Devine, 1986; Watt, 1991). Fourteen dogs with suspected DLSS were evaluated clinically after distraction, and LS joint fusion was performed without laminectomy. Improvements were seen in all cases 2 months after surgery (Slocum and Devine, 1986).

OBSERVATIONS AND CONCLUSION

The reported efficacy of surgical interventions must be interpreted carefully and with knowledge of the variability in clinical diagnosis, treatment selection criteria, treatment modalities, and follow-up assessments. Scientific reports regarding treatment of DLSS have tended to be primarily retrospective studies with diagnostic standards inconsistent among investigators. Retrospective studies by nature are insufficient to evaluate most treatments since these are not randomized, blinded, or multicenter and it is difficult to eliminate bias from the results. As stated above, differences in the criteria for diagnosis are also pivotal, as inaccuracy of survey or contrast radiography for demonstrating neural compression will alter the patient entry criteria. Surgery as the standard of

diagnosis is also misleading because of the difficulty in assessing the degree of compression at surgery. In addition, surgeon bias is possible as a result of the unfavorable connotation associated with negative surgical findings.

We recognize that specific surgical treatment recommendations for DLSS are poorly supported. However, we currently use a combination of decompression, distraction, and fusion. Removal of the ligamentum flavum is performed to allow exploration of the nerve roots. Proliferative tissue is excised, and the LS intervertebral foramina are explored. A partial discectomy is also performed when possible. Distraction of the LS joint is achieved using modified Gelphi's or a lamina spreader. Once reduction of the facet joints is achieved with distraction, cortical screws are placed transarticularly in both facet joints to maintain distraction.

The imaging modalities currently used in veterinary medicine have improved the knowledge of DLSS. Important future considerations should be toward establishing universally agreed diagnostic criteria and scientifically accepted evidence for treatment efficacy. Although veterinary surgeons have described various techniques used to treat DLSS, it is unclear what extent surgery has on outcome. Prospective case-controlled studies with random allocation of treatments is needed.

Vestibular Disease of Dogs and Cats

RODNEY S. BAGLEY, *Pullman, Washington*

Disease of the vestibular system results in some of the most dramatic clinical presentations seen in clinical neurology. The vestibular system is largely responsible for keeping the animal oriented with respect to gravity. Therefore vestibular dysfunction is reflected in malpositioning of the body, including the head, limbs, and eyes. Falling, incoordination, head tilting, nystagmus, and ataxia result. This chapter reviews the more common disease processes affecting the vestibular system of dogs and cats.

ANATOMY

The anatomic components of the vestibular system have been reviewed (deLahunta, 1983). Simplistically, the vestibular system is made up of receptor organs within the ear. These receptor organs sense the static position and movement of the head in relation to the ground (gravity). For integration of static posture, small, weighted bodies (statconia) of the vestibular receptors (macula utriculi and sacculi) within the inner ear are acted on by gravity. Statconia lie within a gelatinous covering. Cilia from the vestibular receptor cells protrude into this gelatinous covering. The force exerted on these statconia results in deflection of the ciliated receptor, thus providing positional information that is integrated centrally.

For detection of head motion, movement of fluid (endolymph) in small tubular structures (semicircular canals) results in motion of cilia on additional receptor cells within terminal dilations (crista ampullaris). This movement of cilia excites the receptor cell that conveys this information through the vestibular nerve to the central components of the vestibular system. Thus the vestibular receptors collect information regarding the movement of the head in space.

Nerve fibers coursing from these peripheral receptors form the vestibular nerve proper. The nerve itself is relatively short. Nerve fibers can then terminate in the vestibular nuclei or within parts of the cerebellum (flocculonodular lobe) associated with vestibular functions, providing the anatomic reason that vestibular-type signs can be seen with cerebellar diseases.

CLINICAL SIGNS OF VESTIBULAR DISEASE

Clinical signs of vestibular dysfunction reflect abnormal orientation of the head, limbs, and eyes. A head tilt, nystagmus, and ataxia are common, regardless of whether

the disease involves the peripheral receptors (peripheral vestibular disease) or the central nuclei, cerebellum, or projection pathways (central vestibular disease). However, the head is usually tilted in the direction of the lesion. With lesions of the caudal cerebellar peduncle, the head is often tilted away from the side of the lesion. An associated ipsilateral hemiparesis is often helpful in lesion localization as to the side of the lesion.

Nystagmus, a characteristic eye movement with a quick and slow phase, is commonly associated with vestibular dysfunction. Nystagmus can be induced normally (oculovestibular response) by turning the head from side to side. The fast phase of eye movement is in the direction that the head is moved. This slow drift and quick reset during sideways movement of the head is normal. In animals with bilateral vestibular disease, the oculovestibular response is absent. When the vestibular system is dysfunctional, the eyes have a tendency to spontaneously drift in the direction of the lesion (slow phase), and through a brainstem reset mechanism the eyes are quickly returned to their initial location (fast phase).

Abnormal nystagmus can occur spontaneously (present at rest) or with abnormal head positions (i.e., positional nystagmus). This latter nystagmus is only present when the head is placed into an abnormal orientation by the examiner. A positional nystagmus is most easily elicited by placing the animal upside down on its back. The direction of the nystagmus is described in relation to the horizontal axis through the palpebral fissure. With a horizontal nystagmus, eye movement is in the direction of this axis. A vertical nystagmus is in the direction perpendicular to this axis. With a rotatory nystagmus, the eye moves around the axis in either a clockwise or counterclockwise direction.

By convention, the direction of the nystagmus is described according to the direction of its fast phase. This can be confusing because the lesion is present on the side of the slow phase of the nystagmus. With peripheral lesions the fast phase of the nystagmus is directed away from the side of lesion. With central lesions the direction of the slow phase in relation to the side of the lesion can vary.

The vestibular system affects limb movement, normally being facilitatory to ipsilateral limb extension. A lack of vestibular input can result in ataxia or falling and rolling. The laterally recumbent animal prefers to lie on the side of the body with the lesion. The ipsilateral limb often has decreased extensor tone, with the opposite side limbs

having increased extensor tone. The animal may circle, usually toward the side of the lesion. Central lesions that affect the vestibular system often involve ascending and descending motor and sensory pathways to the limb. Therefore paresis is common. Because the vestibular influence over limb function is ipsilateral, a brainstem lesion affects the limbs on the same side of the body as the lesion.

Normal vestibular control is also important for maintaining the eye in a normal position within the orbit. Vestibular information is projected through the medial longitudinal fasciculus to cranial nerves III, IV, and VI. If the vestibular input is abnormal, an abnormal eye position (strabismus) may be seen when the examiner moves the head into an aberrant position. This is most readily seen as the animal's head is extended dorsally. When viewed from above, a ventral or ventrolateral strabismus is present in the eye on the affected side. The dorsal sclera of this affected eye is more exposed than in the unaffected eye.

Vomiting and nausea are common in humans with vestibular disease and are more often associated with peripheral vestibular disease. Vomiting is also recognized in animals, more often with acute vestibular dysfunction. Nausea is difficult to assess in animals but may contribute to the anorexia often seen with acute vestibular dysfunction.

NEUROANATOMIC LOCALIZATION

Differentiation as to whether the lesion is central (within the brainstem) or peripheral (within CN VIII proper or its peripheral receptors) is important for selection of appropriate diagnostic tests (Table 239-1). The presence of certain clinical signs is associated with a central vestibular lesion. However, if these signs are not present, a central lesion cannot be excluded. A head tilt, horizontal or rotatory nystagmus, and ataxia can occur with both peripheral and central vestibular disease. A positional vertical nystagmus and limb paresis are the most consistent signs of central vestibular disease. With unilateral central vestibular lesions, hemiparesis may be seen ipsilateral to the lesion. Occasionally a hemiparesis is present on the side

of the body opposite from the direction of the head tilt (paradoxical vestibular syndrome). In this situation the lesion occurs on the side of the body ipsilateral to the hemiparesis.

In dogs with bilateral peripheral vestibular abnormalities, no oculovestibular response is elicited on head movement. The animal often has a wide-based stance. The head is held closer to the ground and may be swung in wide excursions from side to side.

Once the lesion has been localized, appropriate differential diagnoses can be formulated. Unfortunately intracranial lesions occasionally result in signs indicative of a peripheral lesion. Conversely, animals with acute, severe peripheral vestibular dysfunction may be so incapacitated that accurate interpretation of neurologic examination findings may not be possible. Because of these nuances, if the examiner is unsure of location of the lesion, an evaluation for central vestibular disease should occur concurrently with an evaluation for peripheral disease.

PERIPHERAL VESTIBULAR DISEASES

Idiopathic peripheral vestibular disease occurs in both dogs and cats (Schunk, 1990). Older dogs (canine geriatric vestibular disease) and young to middle-aged cats are most commonly affected. Cats in the northeast are commonly affected in late summer and early fall. No cause is defined. In the southeast a similar syndrome is suspected to be caused in cats from eating the tail of the blue tail lizard.

Clinical signs are of an acute peripheral vestibular disorder with nystagmus (horizontal or rotary), head tilt (toward the side of the lesion), rolling, and falling. No other neurologic signs are seen. Initially clinical signs are severe. If Horner's syndrome or facial nerve paresis is also present, other differentials should be considered. Differential diagnosis of peripheral vestibular disease include otitis interna in dogs and cats, middle ear polyps in cats, and neoplasia (squamous cell carcinoma of the middle ear) in both species. Otoscopic examination, bulla radiographs, and other advanced imaging studies (computed tomography [CT], magnetic resonance imaging [MRI]) are normal.

Clinical signs of idiopathic vestibular disease usually improve dramatically in 1 to 2 weeks. The nystagmus usually resolves quickly (within the first few days). Improvements in posture and walking occur within 5 to 7 days, whereas a mild head tilt may remain persistent. Although most animals compensate well, some may have episodic ataxia when performing tasks such as jumping up on furniture. No treatment has proved beneficial, and recurrence is possible.

Otitis media/interna is a common cause of vestibular dysfunction (Kirk and Bonagura, 1995, p. 1128). Most often this is the result of a bacterial infection, from either inward extension from the external ear or migration from the pharynx via the auditory tube. Less commonly infection stems from hematogenous spread. Foreign bodies such as grass awn migration may predispose to severe ear infections.

Clinical signs may reflect primary ear, vestibular, or auditory dysfunction. A painful external ear and/or pain

Table 239-1

Differentiation of Peripheral Versus Central Vestibular Disease

Clinical Sign	Central	Peripheral
Nystagmus		
Spontaneous	Horizontal Rotatory <i>Vertical</i>	Horizontal Rotatory
Positional	<i>Changing</i>	Constant
Head tilt	Present	Present
Cranial nerve deficits	<i>Any other than VII</i>	VII
Horner's syndrome	<i>±</i>	<i>±</i>
Conscious proprioceptive abnormalities	<i>Present</i>	Absent

Italics indicate clinical signs more often associated with central disease.

on opening the mouth are often present. It has been suggested that as many as 50% of animals with otitis media/interna have associated facial nerve involvement. Otoloscopic examination should be used to examine the tympanic membrane. This may be difficult in animals with severe otitis externa before cleansing. The tympanic membrane is often discolored (hyperemic), opaque, and bulging outward with middle ear disease. Clear-to-yellow fluid may be seen behind the membrane. Diagnosis may also be supported by bulla radiographs or advanced imaging studies (Remedios, Fowler, and Pharr, 1991) (Fig. 239-1). Definitive diagnosis is made through culture of the organism via a myringotomy or at surgical exploration.

Tumors of the ear more often occur in older animals. Squamous cell carcinoma and adenocarcinoma are most common. Inflammatory polyps occur in cats. Tumors that extend through the tympanic membrane may be seen during otoscopic examination (Fig. 239-2). Skull radiographs or advanced imaging is necessary to assess the middle and inner ear. However, abnormalities seen with these studies are not always definitive for neoplasia, and tissue diagnosis at surgery is often necessary for accurate assessment. Destruction (lysis) of the bone of the bulla is associated more often with neoplasia than with inflammation. Treatment options include surgical resection/debulking, radiation, and chemotherapies.

Congenital peripheral vestibular disease is seen in German shepherds, Doberman pinschers, English cocker spaniels, and Siamese and Burmese cats. Although often this is an idiopathic condition, congenital peripheral vestibular disease has been associated with lymphocytic labyrinthitis in young Doberman pinschers (Forbes and Cook, 1991). Bilateral congenital vestibular disease is

Fig. 239-2 Otoloscopic view of the external ear of a dog with a head tilt. A clear fluid is overlying a mass. Histologic diagnosis was inflammatory polyp.

seen in beagles and Akitas. Clinical signs include head tilt, ataxia, and, in some, deafness. Signs may remain persistent throughout life or may improve spontaneously. There is no treatment.

Metronidazole toxicity may result in central vestibular signs in both dogs and cats (Dow et al., 1989; Saxon and Magne, 1993). Usually this is associated with high doses of the drug. However, since metronidazole is metabolized by the liver, toxic serum levels can occur with appropriate doses in animals with liver dysfunction. Ataxia is usually the initial clinical sign, progressing to nystagmus and more severe vestibular dysfunction. Clinical signs often reflect central vestibular dysfunction, and morphologic lesions have been found in the brainstem of affected dogs. Serum concentrations of metronidazole will be in the toxic range if measured soon after clinical signs begin. If there is a delay in collecting blood for drug concentrations after the initiation of clinical signs, serum concentrations of metronidazole may be decreased into the normal range even as the clinical signs remain persistent.

Diazepam is often a helpful treatment for metronidazole toxicity. Discontinuation of the drug is imperative. If clinical signs are initially severe, some dogs may die. Other dogs recover completely, usually over 1 to 2 weeks.

Aminoglycosides administered either systemically or topically may cause deafness and vestibular signs (Mansfield, 1990). Streptomycin and gentamicin have the most pronounced effects on the vestibular receptors; whereas neomycin, kanamycin, and amikacin preferentially damage auditory receptors. Chlorhexidine solution used to clean the external ear may result in vestibular abnormalities.

Fig. 239-1 Transaxial, contrast-enhanced T_1 -weighted magnetic resonance image of a dog with otitis externa. Note the contrast enhancing lesion within the right bulla (small arrows). The external ear canal is also enhanced (large arrow). Histologic diagnosis was chronic infection caused by grass and foreign body migration.

Other idiopathic or inflammatory neuropathies may affect the vestibular nerve. Overall these diseases are poorly described and difficult to diagnose definitively. Similarly, a possible relationship exists between some metabolic diseases such as hypothyroidism and a vestibular neuropathy. However, a cause-and-effect relationship is not always established.

CENTRAL VESTIBULAR DISEASES

Tumors of the infratentorial space such as meningiomas and choroid plexus tumors may cause vestibular signs from infiltration or compression of the vestibular nerve (Fig. 239-3). Meningiomas may form a mass or grow in a sheetlike configuration ("en plaque"). Choroid plexus tumors arise around the fourth ventricle, often at the level of the lateral apertures. Diagnosis of an intracranial mass is made with advanced imaging studies. Lesions and associated brain structures are often better seen with MRI versus CT because beam-hardening artifact with the latter commonly obscures structural detail in this area. Surgical debulking or resection of these tumors is ideal but is often hindered by lack of surgical exposure and intimate association with vital brain structures. Radiation may provide some benefit by slowing tumor growth. However, choroid plexus tumors are relatively radiation resistant.

Thiamine deficiency is the most common nutritional deficiency affecting the central nervous system (CNS). This deficiency most often affects cats and results in lesions in the oculomotor and vestibular nuclei, the caudal colliculus, and lateral geniculate. The earliest clinical sign is vestibular ataxia, progressing to seizures with ventral neck flexion and dilated, nonresponsive pupils. Treatment is administration of thiamine, either parenterally or intravenously.

Inflammatory disease can affect the brainstem as well as other areas of the nervous system. These include both infectious and noninfectious etiologies. The incidence of infectious diseases associated with meningitis varies with geographic location. Most meningitis syndromes (60%) in small animals do not have a definable infectious cause. Infectious agents causing brain disease include viruses

(distemper, parvovirus, parainfluenza, herpes, feline infectious peritonitis, pseudorabies, rabies), bacteria, rickettsia (Rocky Mountain spotted fever, *Ehrlichia*), spirochetes (Lyme disease, leptospirosis), fungi (blastomycosis, histoplasmosis, cryptococcosis, coccidioidomycosis, aspergillosis), protozoa (toxoplasmosis, neosporosis), and unclassified organisms (protothecosis).

Specifically, the rickettsia associated with Rocky Mountain spotted fever commonly involves the brainstem, particularly the vestibular system (Greene et al., 1985). Usually there is a history of systemic illness (most often with thrombocytopenia) 5 to 10 days before development of neurologic signs. As the animal's fever is decreasing, neurologic signs appear. There is no mass lesion present on intracranial advanced imaging studies. Occasionally increased contrast enhancement is noted in the choroid plexus area in affected dogs. This must be differentiated from the degree of contrast enhancement normally seen in these structures. Cerebrospinal fluid (CSF) usually contains milder increases in nucleated cells (<50 nucleated cells/ μ l; normal <5 nucleated cells/ μ l) and milder increases in protein concentration (<50 mg/dl; normal <25 mg/dl). Diagnosis is supported by increasing serum titers to the organism, but results often are available after the disease has progressed. Prognosis depends primarily on the severity of clinical signs before treatment. Dogs that are severely obtunded before treatment are less likely to recover. Therefore dogs with clinical features of vestibular disease after a systemic febrile illness associated with thrombocytopenia should be treated with tetracycline or doxycycline before establishing a definitive diagnosis with titers.

Brainstem trauma usually occurs secondary to being hit by a car. Brainstem function can be assessed by evaluation of cranial nerve function, particularly the oculovestibular response. Occasionally dogs have brainstem signs with cranial cervical lesions; therefore manipulation for the oculovestibular response should be made only after assessing for unstable cervical fracture or luxations. An otoscopic examination also may reveal hemorrhage in the ear canals.

Diagnosis is supported by a history of a witnessed traumatic event. Skull fractures may be seen with skull radiography. Advanced imaging studies are used to assess for

Fig. 239-3 Preoperative, T_1 -weighted contrast-enhanced magnetic resonance image (**A**) of a dog with a right head tilt. There is a contrast-enhancing mass in the right cerebellopontine angle (arrow). **B**, Postoperative, contrast-enhanced computed tomography image (3B) at approximately the same level showing resection of the mass (arrow). Histologic diagnosis was a meningioma.

intracranial hemorrhage and edema. With acute trauma (within the first 12 hours), CT may be better at delineating intracranial hemorrhage. Treatment centers around recognizing and treating the pathophysiologic sequelae to brain trauma such as brain edema. Occasionally surgical removal of debris or hemorrhage is necessary to stabilize intracranial pressure.

Vascular diseases that involve the central vestibular areas and associated cerebellum are uncommon. However, with the advent of advanced imaging studies, antemortem diagnosis should be improved.

DIAGNOSTIC TESTING

If a lesion is suspected to involve the central vestibular structures (forebrain, brainstem, or cerebellum) in small animals, an advanced imaging study such as CT or MRI is used to assess the structural integrity of these areas. These studies are noninvasive but do require anesthesia in all but the comatose animal. Survey radiographs of the skull are useful in instances of skull fracture or middle ear (bullae) disease; however, they do not allow for assessment of nervous system parenchyma. If peripheral disease is suspected, a thorough otoscopic examination, preferably while the animal is anesthetized, is mandatory.

CSF analysis is helpful primarily to determine the presence of inflammatory diseases. In general, collection of spinal fluid caudal to the level of the lesion is most accurate for diagnosis. Fluid is analyzed for cellularity, protein content, and cell morphology. Although CSF analysis is often helpful in determining the presence of nervous system disease, used alone it does not often lead toward a specific etiologic diagnosis. Titers to specific infectious agents can be measured in CSF to assess for intrathecal production of antibody. However, in the presence of blood-brain barrier breakdown, antibodies may nonspecifically cross into the CSF from the systemic circulation. In this instance correlation of the CSF to serum titer may be necessary. An increased antibody titer in the CSF relative to the serum antibody titer suggests local production of antibodies within the CNS, suggestive of actual CNS infection. Protein electrophoresis on CSF can give additional information concerning integrity of the blood-brain barrier and local production of immunoglobulins.

Recording the brainstem auditory potential (BAEP or BAER) may be helpful in determining the presence of intact hearing pathways and may also provide some information about the integrity of central (brainstem) projection pathways associated with hearing (Steiss, Cox, and Hathcock, 1994; Fischer and Obermaier, 1994).

Surgical biopsy is often necessary for definitive antemortem diagnosis of structural intracranial disease. This is more difficult in the infratentorial space because surgical exposure, especially of ventrally located lesions, is often incomplete. Surgical exposure of lesions at the cerebellopontine angle area may be increased by occlusion of the overlying transverse sinus. The limited access to this area often hinders complete lesion resection.

For lesions of the ear canal and bulla, lateral ear canal resection and bulla osteotomy, respectively or in combination, are useful for biopsy, lesion resection, and drainage

of infected tissue. If these procedures are performed for ear exploration in animals without vestibular signs, head tilts, ataxia, and nystagmus may result from damage of the vestibular structures during the surgical procedure itself.

TREATMENT

Specific treatments can best be recommended after a definitive diagnosis is made. If intracranial tumors are diagnosed, specific treatments such as surgical debulking/resection and radiation therapy may be helpful. With primary inflammatory diseases the etiologic organism should be determined, if possible, and specific treatments directed toward killing the organism. With Rocky Mountain spotted fever, tetracycline and doxycycline can eliminate the vestibular signs (Kirk and Bonagura, 1995, p. 293). With toxoplasmosis a combination of clindamycin and trimethoprim/sulfadiazine often improves or eliminates clinical signs. Noninfectious, inflammatory CNS disease will be responsive to corticosteroids initially. Granulomatous meningoencephalitis has also been treated with radiation.

Nonspecific treatments include protecting the eyes from damage, especially if there is an associated facial nerve deficit or if the animal is lateral recumbent and rolling into the ground. Antihistamines (Kirk and Bonagura, 1995, p. 48) such as diphenhydramine (1 to 2 mg/kg PO or IV every 12 to 24 hours) have been useful in decreasing anxiety, anorexia, and in some instances the severity of the associated head tilt and nystagmus.

Treatment of Canine Chiari-Like Malformation and Syringomyelia

CLARE RUSBRIDGE, *London, England*
CURTIS W. DEWEY, *Ithaca, New York*

Chiari-like malformation (CM) is a condition characterized by a mismatch between the caudal fossa (skull) volume and its contents, the cerebellum and brainstem. The neural structures are displaced into the foramen magnum, obstructing cerebrospinal fluid (CSF) movement. A consequence of this is syringomyelia (SM) in which fluid-filled cavities develop within the spinal cord (Fig. 240-1). The primary clinical sign of CM/SM is pain, caused either by obstruction of the CSF pulse pressure and/or a neuropathic pain syndrome resulting from damage to the spinal cord dorsal horn. This disease has also been referred to as *occipital hypoplasia* and *caudal occipital malformation syndrome* (COMS) (Dewey et al., 2005). CM/SM is sometimes erroneously confused with *Arnold Chiari malformation* (cerebellar and medulla herniation associated with myelomeningocele) and *occipital dysplasia* (incomplete ossification of the supraoccipital bone).

Fig. 240-1 Midsagittal T2-weighted MRI of the brain and upper cervical spinal cord from a 3-year-old female CKCS with syringomyelia (asterisks) that first developed signs of pain at 1.7 years old. Clinical signs included shoulder scratching at exercise and when excited. She would not tolerate her right ear to shoulder area to be touched or groomed. She frequently screamed, and she became distressed whenever her owners tried to exercise her. She also had a mild pelvic limb weakness. She was managed with a foramen magnum decompression and despite persistence of the syrinx made a satisfactory postoperative recovery that was maintained for 1.8 years. Following this deterioration she was managed medically for a further 3.8 years and currently is 7 years old.

PATHOGENESIS

The pathogenesis of canine CM/SM is not fully understood. An important contributory factor is thought to be an inadequate small caudal fossa volume that early observations suggested is caused by a relatively short basioccipital bone (i.e., an inappropriately short skull base) (see Fig. 240-1). However, it is likely there are other unidentified anatomic or environmental factors. Studies comparing intracranial dimensions did not demonstrate a significant difference between the size of the caudal fossa in cavalier King Charles spaniels (CKCSs) with and without SM (Carruthers et al., 2006; Cerda-Gonzalez, Olby, and Pease, 2006).

The precise pathogenetic mechanism of development of SM is much debated (reviewed by Rusbridge, Greitz, and Iskandar, 2006; Greitz, 2006), although there is increasing agreement that the syrinx fluid is not CSF but most likely extracellular fluid that accumulates within the central canal or spinal cord substance as a consequence of abnormal pressure differentials between the spinal cord and subarachnoid space (Levine, 2004; Greitz, 2006). Early proposals for the pathogenesis of SM such as the *water-hammer* and *suck effect* theory now seem unlikely because these rely on the presence of a connection between the fourth ventricle and central canal in addition to a lower pressure system within the syrinx relative to the ventricle and subarachnoid space. The *intramedullary pulse pressure* theory of SM postulates that the obstruction of CSF flow results in relative increase in intrathecal pressure and decrease in subarachnoid pressure, the consequence of which is repeated mechanical distention of the spinal cord. This in turn results in dilation of the central canal and accumulation of extracellular fluid, which eventually coalesces into cavities (Fig. 240-2).

Incidence

The CKCS is overwhelmingly overrepresented for cases of CM/SM. An estimated 95% of the population have CM, and as many as 50% have CM/SM, with the proportion of affected dogs increasing with age. There is no color or sex predisposition. Since a shortened skull is a risk factor, any breed with a degree of brachycephalism

Fig. 240-2 The intramedullary pulse pressure theory of syringomyelia. Chiari malformation and obstruction of the foramen magnum prevent transmission of the systolic CSF pulse pressure wave to the distal CSF spaces. The pulse pressure is instead transmitted and reflected into the spinal cord tissues, resulting in a relative increase in intrathecal pressure and decrease in subarachnoid pressure. In addition, because of the partial obstruction, the CSF displaced by each systole is forced through the narrower opening, resulting in high-velocity jets of CSF ventrally within the foramen magnum. These high-velocity jets decrease the hydrostatic pressure in the subarachnoid space (Venturi effect / Bernoulli theorem). The changes in pressure have a “suction effect” on the spinal cord. Repeated spinal cord distention results in extracellular fluid accumulation and eventually syringomyelia.

and/or miniaturization could potentially be predisposed to CM/SM. To date the condition has been also reported in King Charles spaniels, Brussels griffons, Yorkshire terriers, Maltese terriers, Chihuahuas, miniature dachshunds, miniature/toy poodles, bichon frise, pugs, Shih Tzus, Pomeranians, Staffordshire bull terriers, a Boston terrier, French bulldogs, a Pekingese, and a miniature pinscher. Recent studies suggest that 35% of SM-affected dogs have clinical signs of the condition. The youngest reported dogs with SM have been 12 weeks old. Dogs may be presented at any age, although the majority of dogs (approximately 45%) develop first signs of the disease within the first year of life and approximately 40% of cases have first signs between 1 and 4 years old. As many as 15% develop signs as mature dogs, with the oldest reported case first developing signs of disease at age 6.8 years. Because of the vague nature of signs in some cases and lack of awareness about the disease, there is often a considerable time period (mean 1.6 years) between the onset of signs and confirmation of a diagnosis.

Clinical Signs

The most important and consistent clinical sign of CM/SM is pain; however, this may be difficult to localize on clinical examination and, because it is often intermittent, may be dismissed by owners or veterinarians. Therefore historical signs of pain should be considered seriously in predisposed breeds. Owners may describe postural pain; for example, affected dogs may suddenly scream and/or lie with the head on the ground between the paws after jumping up or during excitement. It is also common to sleep with the head in unusual positions (e.g., elevated). Discomfort often appears worse in the evening and early morning or when the dog is excited and can be associated with defecation or may vary with weather conditions. Some of the signs of SM such as posture-related pain could be explained by obstruction to CSF flow, but

SM also results in a neuropathic pain syndrome probably caused by damage to the spinal cord dorsal horn. Affected dogs behave as if they experience allodynia (i.e., pain arising in response to a nonnoxious stimulus); for example, they appear to dislike touch to certain areas of the skin (ear, neck, forelimb, or sternum) and may be unable to tolerate grooming or a neck collar. Pain is positively correlated with syrinx width (Fig. 240-3); that is, dogs with a wider syrinx are more likely to experience discomfort, and dogs with a narrow syrinx may be asymptomatic, especially if the syrinx is symmetric and not deviated into the dorsal horn. A dog with a wide syrinx may also scratch, typically on one side only, while it is walking and often without making skin contact; such behavior is often referred to as an *air guitar* or *phantom* scratching. This sign is highly suggestive of dysesthesia (i.e., a spontaneous or evoked unpleasant abnormal sensation). Humans with SM-associated dysesthesia describe painful, burning itching and/or an intense sensation suggesting insects crawling on the skin.

Dogs with a wide syrinx are also more likely to have scoliosis. This is likely to relate to damage to the dorsal grey column and a unilateral loss of proprioceptive information.

Fig. 240-3 T2-weighted transverse image through a wide syrinx (asterisk) demonstrating the asymmetric involvement of the right dorsal horn.

Scoliosis is more common in dogs less than 1 year old and may be the first clinical signs of SM, appearing before signs of neuropathic pain develop. In many cases the scoliosis slowly resolves despite persistence of the syrinx.

SM may result in other neurologic deficits such as thoracic limb weakness and muscle atrophy (caused by ventral horn cell damage) and pelvic limb ataxia and weakness (caused by white matter damage or involvement of the lumbar spinal cord by the syrinx). Seizures, facial nerve paralysis, and deafness may also be seen; however, no direct relationship has been proven, and this association may be circumstantial.

CM alone appears to cause facial pain in some dogs, with owners describing ear and facial rubbing/scratching. It has been proposed that CM and direct compression of the medulla can result in a disorder of sensory processing and a pain syndrome (Thimineur et al., 2002). In this circumstance it can be difficult to be certain that the CM, as apposed to ear, oral or skin disease, is the cause of the distress, especially since CM is a common incidental finding in the CKCS breed.

Clinical Course

Progression of disease is variable. Some dogs remain stable or deteriorate minimally over years. Other affected dogs can be severely disabled by pain and neurologic deficits within 6 months of the first observed signs.

Diagnosis

Magnetic resonance imaging (MRI) is essential for diagnosis and determining the cause of SM (see Fig. 240-1). With CM/SM the cerebellum and medulla extend into or through the foramen magnum, which is occluded with little or no CSF around the neural structures. The size of the cerebellar herniation is not correlated with severity. Typically there is ventricular dilation. SM is indicated by fluid-containing cavities within the spinal cord. The upper cervical and thoracic segments typically are most severely affected. The shape of the cavity may be complex with septation (i.e., haustria) and generally involves a portion of the central canal at some level. Maximum syrinx width is the strongest predictor of pain, scratching behavior, and scoliosis; 95% of CKCSs with a maximum syrinx width of 0.64 cm or more will have associated clinical signs.

Laboratory tests such as hematology, serum biochemistry, and urinalysis are only useful to eliminate other differentials or to establish that there is no reason to preclude surgical or medical management. Radiographs have limited value. In severe cases cervical images may suggest widening of the vertebral canal, especially in the C2 region, and/or scoliosis. Flexed and extended images of the neck can be used to rule out vertebral abnormalities such as atlantoaxial subluxation and to indicate the likelihood of intervertebral disk disease. Ultrasonography through the cisterna magnum may confirm cerebellar vermis herniation; however, since CM is so common in the CKCS, this information has limited value. Likewise a syrinx may be identified if within the cranial cervical segment; however, failure to detect a syrinx does not eliminate the possibility

of one more caudally. CSF analysis may be useful to rule out inflammatory diseases. Sampling requires experience because there is a high risk of inaccurate needle placement. Myelography is contraindicated for the same reason. CM/SM does not appear to increase risk of anesthesia. Preliminary data suggest that asymmetric brainstem auditory evoked-response (BAER) test results are predictive of the presence of CM in mature CKCSs; whether or not this test will have wide use as a screening tool for early diagnosis of the disorder is unknown at this time.

Differential Diagnosis

The most important differential diagnoses are other causes of pain and spinal cord dysfunction such as intervertebral disk disease, CNS inflammatory diseases such as granulomatous meningoencephalomyelitis, vertebral abnormalities such as atlantoaxial subluxation, neoplasia, and diskospondylitis. When scratching or facial/ear rubbing is the predominant clinical sign, ear and skin disease should be ruled out. The scratching behavior for SM is classically to one distinct area. It is a common *incidental* finding for CKCSs to have a mucoïd material in one or both tympanic bullae, and in most cases this is not associated with clinical signs. Some dogs with scoliosis appear to have a head tilt, which could be confused with vestibular dysfunction. If in doubt, cervical radiographs can confirm scoliosis.

Treatment and Prognosis

The main treatment objective is pain relief. The most common surgical management is cranial cervical decompression (also described as foramen magnum or suboccipital decompression) establishing a CSF pathway via the removal of part of the supraoccipital bone and dorsal arch of C1 (Fig. 240-4). This may be combined with a durotomy (incision of the dura with or without incision of subarachnoid meninges) with or without patching with a suitable graft material such as biocompatible collagen matrix (Vet BioSIST, Cook/Global Veterinary Products). Cranial cervical decompression surgery is successful in reducing pain and improving neurologic deficits in approximately 80% of cases, and approximately 45% of cases may still have a satisfactory quality of life 2 years after surgery (Rusbridge, 2007). However, surgery may not adequately address the factors leading to SM, and the syrinx appears persistent. The clinical improvement is probably attributable to improvement in CSF flow through the foramen magnum. In some cases scarring and fibrous tissue adhesions over the foramen magnum seem to result in reobstruction, and as many as 50% of cases can eventually deteriorate (Rusbridge, 2007). This can be as early as 2 months after surgery. Recently a cranioplasty procedure used in human cranial cervical decompression surgery to decrease the incidence of postoperative compressive scar tissue formation has been adapted for use in dogs. The procedure entails placement of a plate constructed of titanium mesh and polymethylmethacrylate on preplaced titanium screws bordering the occipital bone defect (Fig. 240-5). Although results are preliminary (based on

Fig. 240-4 Cranial cervical decompression. The dura and arachnoid meninges have been incised and are supported by a stay suture. The spinal cord and the cerebellar vermis can be visualized through the meningeal defect. The dog's head is at the top of the picture.

21 dogs to date), the procedure is well tolerated and may have decreased the need for reoperation because of excessive postoperative scar tissue formation (Dewey et al., 2006). An alternative method of managing SM is direct shunting of the cavity. In humans this is not a preferred

technique for management of CM/SM because long-term outcome is poor as a result of shunt obstruction and/or spinal cord tethering. However, the short-term results are reasonable, with syrinx collapse occurring in a majority of human cases. There has been a single report of syringo-subarachnoid shunting in a dog using an equine ocular lavage tube (Cook/Global Veterinary Products). However, postoperative MRI revealed that SM was still prominent although there was a clinical improvement in the dog (Skerritt and Hughes, 1998).

Because of the persistence of SM and/or spinal cord dorsal horn damage, it is likely that the postoperative patient will also require continuing medical management for pain relief; in some patients medical management alone is chosen because of financial reasons or owner preference. Three main drug categories are used for treatment of CM/SM: drugs that reduce CSF production; analgesics; and corticosteroids (Fig. 240-6). If the dog's history suggests postural pain or discomfort relating to obstruction of CSF flow, a trial of a drug that reduces CSF pressure (e.g., furosemide, cimetidine, or omeprazole) is appropriate. These drugs also can be useful when it is difficult to determine if the cause of discomfort is CM versus, for example, ear disease. CSF pressure-reducing drugs may be sufficient to control signs in some dogs, but additional analgesics are likely to be necessary for an individual with a wide syrinx. In this circumstance we suggest that non-steroidal antiinflammatory drugs are the medication of first choice partly because there are several licensed products. However, for dogs with signs of neuropathic pain (i.e., allodynia and scratching behavior [suspected dysesthesia]), a drug that is active in the dorsal horn is more likely to be effective. Because gabapentin has established use in veterinary medicine, we suggest that this is the drug of first choice, but amitriptyline or pregabalin may also be suitable. Corticosteroids are an option if pain persists or when available finances prohibit the use of other drugs. Because the mechanisms of development of neuropathic pain are multifactorial, appropriate polypharmacy is likely to be more effective than treatment with

Fig. 240-5 Postoperative images following cranioplasty demonstrating surgical placement of a titanium mesh/polymethylacrylate plate on preplaced titanium screws at the border of the occipital bone defect.

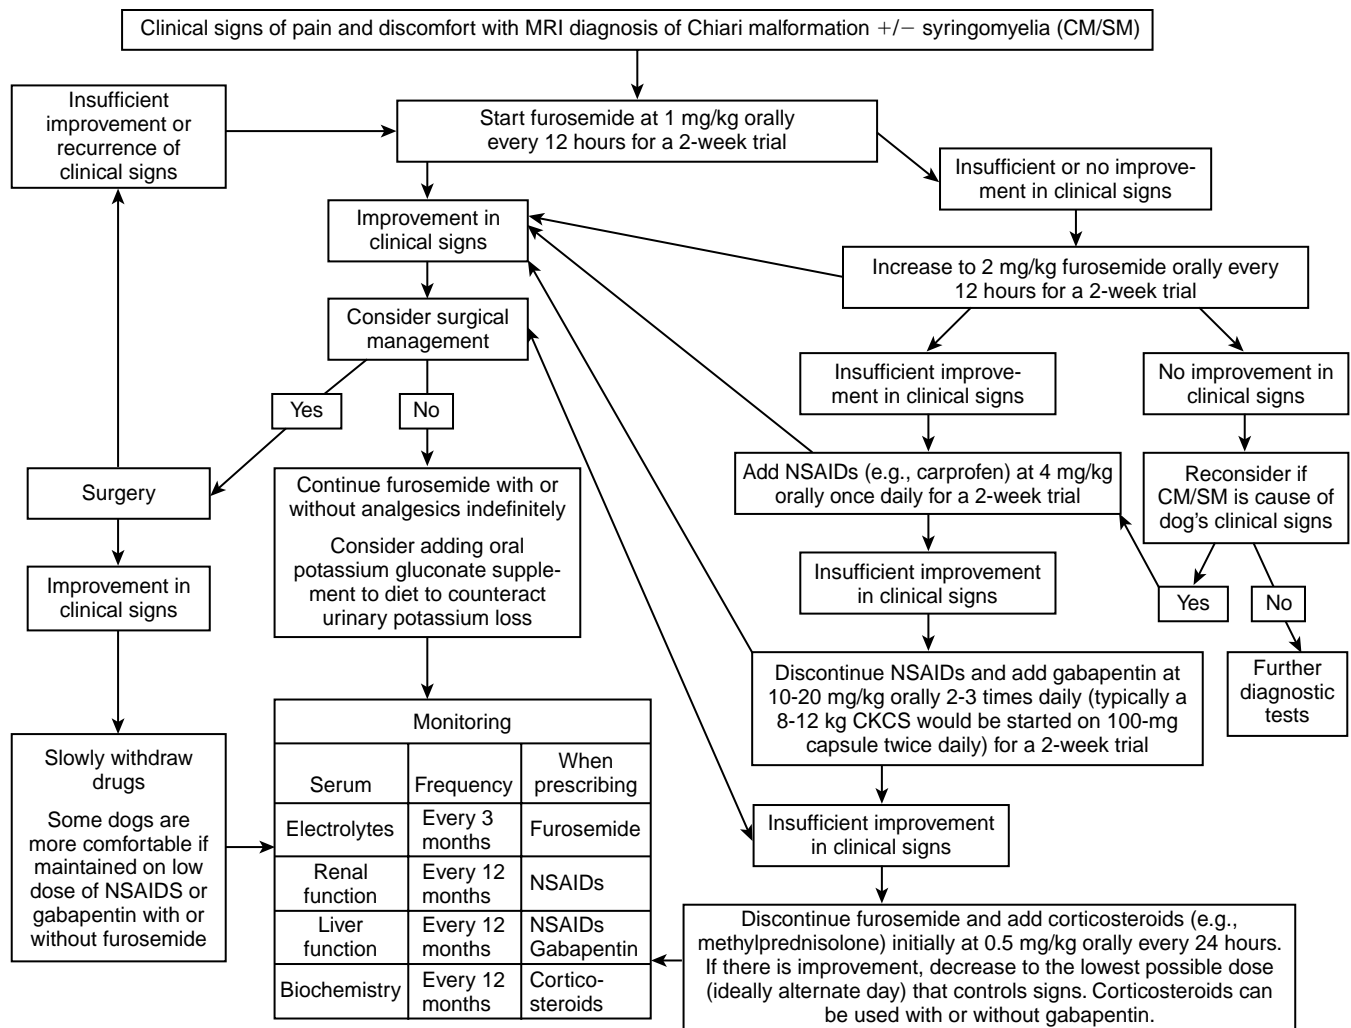

Fig. 240-6 Treatment algorithm for the management of Chiari malformation with or without syringomyelia in the dog. (From Rusbridge C et al: Current concepts in pathogenesis, diagnosis, and treatment, *J Vet Intern Med* 20:469, 2006.)

single agents. Anecdotally acupuncture and alphasonic treatments have been reported to be useful adjunctive therapy in some cases. The dog's activity need not be restricted, but the owner should understand that the dog may avoid some activities and grooming may not be tolerated. Simple actions (e.g., raising the food bowl and removing neck collars) can also help.

Prognosis for CM/SM managed medically is guarded, especially for dogs with a wide syrinx or with first clinical signs before 4 years of age. Study of a small case series (14 CKCSs) managed conservatively for neuropathic pain suggested that 36% were eventually euthanatized as a consequence of uncontrolled pain. However, 43% of the group survived to be older than 9 years of age (average life expectancy for a CKCS is 10.7 years). Most dogs retain the ability to walk, although some may be significantly tetraparetic and ataxic.

Genetics and Breeding Recommendations

CM/SM in the CKCS can be traced back to two United Kingdom bitches from the post-World War II era, which were foundational dogs for the modern breed "created"

from the shorter-nosed King Charles spaniel. A CKCS genome scan is currently underway with the hope of identifying the causal genes. The mode of inheritance, including the number, identity, and relative contribution of the causative genes, is not yet determined; however, preliminary results from the genome have suggested some interesting regions that warrant further investigation. However, because of the ubiquity of the condition within the CKCS breed, this is a complex task, and focus is now centering on comparison with sporadic cases in other breeds. The etiology of both conditions could be further complicated by variable penetrance of the various genotypes and the involvement of environmental factors. Current breeding recommendations for CKCSs concentrate on removal of dogs with early-onset SM (i.e., within the first 2.5 years of life) from the breeding pool (for precise recommendations and grading system). This involves MRI screening of potential breeding stock and therefore is a costly process. The aim of current breeding recommendations is to limit the number of severely affected dogs rather than eliminate the disease from the CKCS population. Because of the number of affected dogs, there is a danger that very restrictive breeding practices will further

narrow the gene pool and other diseases will emerge. It should also be borne in mind that absence of SM in a young dog does not exclude the possibility that it will develop with time.

Treatment of Autoimmune Myasthenia Gravis

G. DIANE SHELTON, *La Jolla, California*

The name *myasthenia gravis* (MG) was originally given to a human disease that was frequently fatal. As recently as 30 years ago, 25% of patients died of this disease. Canine MG has also been associated with a high death rate and, in many older textbooks of veterinary medicine, a poor prognosis for recovery. We now know that, with early recognition of the disease, a correct diagnosis, and appropriate treatment, the prognosis for a relatively normal quality of life and life span is favorable in both human and canine MG.

Canine MG is the most common neuromuscular disease diagnosed in my laboratory. Feline autoimmune MG occurs much less frequently but has a higher incidence of a cranial mediastinal mass (25.7%) than canine MG (3.4%). The spectrum of clinical presentations in both species is broad and variable; thus autoimmune MG should be high on the list of differential diagnoses for any dog or cat presenting with focal or generalized neuromuscular weakness, megaesophagus, or dysphagia. In-depth discussions of the diversity of clinical presentations in canine and feline MG are in the literature (Shelton and Lindstrom, 2001; Dewey 1997; Shelton, Schule, and Kass, 1997; Shelton, Ho, and Kass, 2000; Shelton, 2002).

The onset of clinical signs commonly is acute in nature, occurring only a few days to a few weeks before presentation. Ideally a serum sample should be collected for acetylcholine receptor (AChR) antibody testing, and the diagnosis confirmed before initiation of therapy. The gold standard for the diagnosis of autoimmune MG continues to be the demonstration of autoantibodies against muscle AChRs by immunoprecipitation radioimmunoassay. The assay is specific and sensitive and documents an autoimmune response against muscle AChRs. Although seronegative MG occurs in approximately 2% of dogs with generalized MG, false-positive results are rare. The edrophonium chloride challenge (Tensilon, Enlon, 0.1 to 0.2 mg/kg in dogs and 0.25 to 0.5 mg/kg in cats intravenously) should also be performed since a dramatic positive test would give a presumptive diagnosis of MG and allow initiation of therapy before serologic confirmation. A negative edrophonium chloride challenge should not eliminate a diagnosis of MG. In addition, a subjective improvement in muscle strength may be found with other neuromuscular diseases; thus, unless the response is dramatic, the edrophonium chloride challenge test should not be used alone to confirm a diagnosis. Because of the propensity of dogs with MG to develop aspiration pneumonia, autoimmune MG is one disease in which a delay in obtaining a diagnosis or assuming the wrong diagnosis can result in a fatal outcome.

No single treatment regimen is ideal for all cases of MG. Choices must be made among the therapeutic options, with the goal of obtaining the best result while keeping the risks and side effects as low as possible. Each case needs an individual treatment plan, which may have to be changed from time to time as determined by the stage of the disease and response to treatments. For discussion of available treatments, autoimmune MG will be divided into focal (group 1), generalized (group 2), acute fulminating (group 3), and paraneoplastic (group 4) forms. Unlike human MG in which treatments are usually life-long, dogs with MG routinely go into spontaneous remission, if they survive the initial month following onset of clinical signs and do not have a thymoma (Shelton and Lindstrom, 2001).

SUPPORTIVE CARE

General supportive care and dedicated owners are integral parts of treatment for all groups of MG patients. The owners should be advised that treatment for MG may be for as short as a few months or need to be continued for several months to a couple of years, depending on the severity of disease. Differentiation of vomiting from regurgitation and recognition of esophageal dilation or pharyngeal weakness are critical. As in any dog with esophageal dilation, altered feeding procedures, including elevation of food and water or placement of a gastrostomy tube, should be used to facilitate adequate hydration, nutrition, and drug delivery. If there is a delay in recognition of megaesophagus, inadequate nutrition and poor hydration may occur, which could worsen the clinical status of the animal. Nutritional support can be expected to decrease morbidity and improve immune status. Aspiration pneumonia should be treated aggressively (see Chapter 149). In cases of acute fulminating MG, referral of patients to centers with intensive care facilities is optimal.

Cholinesterase Inhibitors

Cholinesterase inhibitors are the cornerstone of treatment for MG and are advised for all patient groups. These drugs result in improved muscle strength by decreasing the hydrolysis of acetylcholine (ACh) at the neuromuscular junction. This allows for a greater number of ACh molecules to bind to and activate AChRs on the postsynaptic membrane, prolongs the action of ACh, and enhances neuromuscular transmission. Cholinesterase inhibitors do not treat the underlying aberrant immune response

and thus do not modify the course of the disease, but they do control the clinical signs. In the case of canine non-thymomatous MG, this is not a problem, since the natural course of disease is to go into remission in the absence of immunosuppression. If an optimal response to therapy is obtained and there is return of normal limb muscle strength and decreased or resolved regurgitation, supportive care and management of megaesophagus, anticholinesterase drugs, and time may be all that is required.

Pyridostigmine bromide (Mestinon, 1 to 3 mg/kg PO q8-12h) and neostigmine bromide (Prostigmin, 2 mg/kg/day administered orally in divided doses to effect) are the most commonly used cholinesterase inhibitors; the former is preferred in most clinical situations because of its longer duration of action and fewer cholinergic side effects. The dosage must be adjusted individually for each animal, depending on the response to the drug and tolerance of the side effects. Pyridostigmine bromide is available in syrup, tablet, and time-released forms. The syrup form may be optimal for dosing in smaller breeds of dogs but should be diluted 50:50 in water before use because gastric irritation may result if it is given straight. For critical animals in which oral dosing is not possible, constant rate infusion of pyridostigmine bromide (0.01 to 0.03 mg/kg/hour) may be used until oral feedings are resumed or a feeding tube is placed. For dosing in cats, pyridostigmine bromide (0.1 to 0.25 mg/kg q24h) has been recommended.

Side effects of cholinesterase inhibitors result from excessive cholinergic stimulation following the accumulation of ACh at muscarinic receptors of smooth muscle, autonomic glands, the central nervous system, and nicotinic receptors of skeletal muscle. Bradycardia, which results from excessive vagal activity, is seen almost exclusively after parenteral injections of ACh inhibitors. Gastrointestinal side effects may occur after administration by any route and include nausea, vomiting, abdominal cramping, loose stools, or overt diarrhea. Increased bronchial and oral secretions may be a problem if dysphagia is present. Adverse effects may be reduced by administering small doses of atropine or having the animal take medication after meals when feasible.

Overtreatment with cholinesterase inhibitors can result in excessive accumulation of ACh at the neuromuscular junction, with worsening of weakness as a result of depolarization or desensitization of the postsynaptic membrane. Any increase in anticholinesterase medication that does not produce clear-cut improvement in muscle strength should be promptly reversed.

Corticosteroids

If myasthenic animals cannot be managed successfully with supportive care and cholinesterase inhibitors alone, corticosteroids may be added carefully. Corticosteroids have been shown to be of benefit in human MG and may improve the long-term prognosis in some cases of canine MG. However, the side effects may be life threatening. Glucocorticoids result in polydipsia and polyphagia in an animal that may have difficulty swallowing or is regurgitating. In addition, there is an increased susceptibility to infection. Increased weakness often occurs early in the

course of steroid treatment, requiring hospitalization and sometimes intensive medical care with respiratory support. To prevent the initial steroid-induced weakness, low-dose prednisone therapy has been recommended in mild and moderately affected human myasthenic patients. I have also recommended a similar therapeutic approach for myasthenic dogs in groups 1 and 2. Antiinflammatory dosages (0.5 mg/kg PO q24h), not immunosuppressive dosages, of corticosteroids are suggested. Relative contraindications for corticosteroid therapy include severe obesity, diabetes mellitus, uncontrolled hypertension, gastrointestinal ulcerations, and ongoing infections or aspiration pneumonia.

Although myasthenic cats can be treated successfully with anticholinesterase drugs, it is my impression that cats generally respond better to corticosteroid therapy. Unlike the case in dogs, exacerbation of muscle weakness and other unwanted side effects may not occur as frequently in myasthenic cats treated with high doses of corticosteroids.

Immunosuppressive Drugs

Other immunosuppressive drugs have not been studied adequately in canine and feline MG, and there are only a few case reports suggesting effectiveness. Clearly, controlled clinical trials are warranted. Since most cases of canine or feline MG can be managed successfully with anticholinesterase drugs alone or in combination with prednisone, most of these immunosuppressive drugs should be reserved for severe, nonresponsive forms of MG. Disadvantages of these agents are the time it takes for improvement to begin, the side effects, the expense, and the need for chronic administration (Kent, 2004).

Azathioprine

Azathioprine is the most frequently used immunosuppressive agent in MG after prednisolone. Side effects are related to gastrointestinal and myelosuppressive toxicity. A complete blood cell count should be performed 7 to 10 days after initiation of therapy and monthly thereafter. Azathioprine may be used as an alternative to prednisone when the latter drug is relatively contraindicated and when a less rapid response to therapy is acceptable. Azathioprine may also be used for its "steroid-sparing" effects in patients who have developed unacceptable side effects to prednisone, when it has not been possible to reduce the dose of prednisone to acceptable levels, or when the response to prednisone has not been satisfactory. The recommended dosage is 1.1 to 2.2 mg/kg PO every 24 hours or every other day. Since azathioprine can result in neuromuscular blockade in cats, its use is not recommended.

Cyclophosphamide

Cyclophosphamide can cause severe leukopenia, specifically neutropenia, and routine complete blood counts should be performed every 7 to 10 days after administration. Gastrointestinal disturbances can also occur. Sterile hemorrhagic cystitis is another serious side effect of cyclophosphamide, which can occur not only with prolonged administration but after a single dose. This drug has not

been evaluated in canine MG, and, given the serious side effects, the risks do not outweigh the benefits.

Cyclosporine

Cyclosporine has been used in a variety of immune-mediated diseases in the dog but has not been evaluated specifically for the treatment of MG. In human MG cyclosporine is used in patients who are candidates for immunosuppression but who cannot take or who have not responded satisfactorily to azathioprine. It has been used as the primary immunosuppressant in human MG and with prednisone, which permits use of lower corticosteroid doses. The maximum response is usually seen within 3 to 4 months. Suggested dosage ranges for canine immune-mediated diseases are from 5 to 10 mg/kg/day divided into two doses. Side effects include vomiting, diarrhea, weight loss, gingival hyperplasia, and involuntary shaking. Although it is nephrotoxic, dogs seem relatively resistant to this side effect.

Mycophenolate Mofetil

Although mycophenolate mofetil (MMF) has been widely used in human medicine, reports in veterinary medicine have been limited to its use in a case of immune-mediated glomerulonephritis and in a dog with MG. At a dosage of 20 mg/kg every 12 hours gastrointestinal signs may be observed, including vomiting, diarrhea, and anorexia, which are dosage related. For this reason, in patients with MG a 50% reduction in MMF dosage should be made once significant improvement or resolution of clinical signs is noted.

Thymectomy

Most human neurologists recommend thymectomy in their MG patients, although no controlled clinical trial has proven this to be of significant benefit. In human patients there is a high incidence of thymic hyperplasia, which in my experience has only rarely been identified in canine or feline myasthenic patients. In canine and feline MG thymectomy should be reserved for cases of confirmed MG and a cranial mediastinal mass (group 4: paraneoplastic MG). It is my opinion that all animals with a cranial mediastinal mass should be tested for MG before surgical removal. Weakness may become clinical after the surgery, and knowing the antibody status before surgery should aid in therapeutic management. If a cranial mediastinal mass can be removed completely, the AChR antibody titer should return to the reference range, and clinical signs of MG should resolve. If the mass cannot be removed completely, the antibody titer would remain positive, and treatment for MG would need to be continued. Specific treatments would be similar to that of either group 2 (preceding paragraphs) or group 3 (following paragraphs).

Acute Fulminating Myasthenia Gravis

Management of acute, severe generalized MG (group 3: acute fulminating MG) can be difficult and ideally should be performed in intensive care facilities (King and Vite, 1998). In humans expensive short-term treatment modal-

ities such as plasma exchange (plasmapheresis) and intravenous immunoglobulin are commonly used; however, because of the expense and technical difficulty of performing these therapies, they are not commonly used in veterinary medicine. Ventilatory support and placement of a feeding tube are usually required. Respiratory failure, either from ventilatory failure caused by weakness in the intercostal muscles or diaphragm or by severe aspiration pneumonia, may be the most common cause of death in dogs with acute fulminating myasthenic crisis. If possible, cultures should be obtained from the respiratory tract by tracheal wash, and broad-spectrum intravenous antibiotics should be instituted immediately. Aminoglycosides and ampicillin should be avoided because of possible detrimental effects on neuromuscular transmission.

For critical animals in which oral medication is not possible, a constant rate infusion of pyridostigmine bromide (0.01 to 0.03 mg/kg/hour) may be used until oral feedings are resumed. Alternatively anticholinesterase therapy can be administered through a feeding tube.

Myasthenic crisis may be precipitated by concurrent infection or high doses of daily prednisone. Corticosteroids should be avoided initially in patients with overwhelming aspiration pneumonia. Once an infection has been controlled, corticosteroids or other immunosuppressive agents such as azathioprine, cyclosporine, or mycophenolate can be added to the regimen, if necessary. High-dose intravenous methylprednisolone sodium succinate therapy may be of benefit in severe cases of MG without worsening of muscle weakness. In one study of 15 human patients, 2g of methylprednisolone sodium succinate was given intravenously every 5 days for a total of 15 days. Satisfactory improvement without exacerbation of muscle weakness occurred in 10 of 15 patients (Arsura et al., 1985).

MONITORING THE COURSE OF AUTOIMMUNE MYASTHENIA GRAVIS

Although a positive AChR antibody titer is diagnostic of autoimmune MG, there is a poor correlation between the severity of the disease and the antibody concentration. However, in the absence of immunosuppression, determination of serial AChR antibody titers in an individual animal is a good indicator of disease status and should help determine duration of treatment. As long as the AChR antibody titer remains positive, treatment should be continued. In my laboratory there has been an excellent correlation between resolution of clinical signs, including megaesophagus, and return of AChR antibody titers to within the reference range. Monitoring the AChR antibody titer is also suggested in paraneoplastic MG since it gives a good indication as to whether a cranial mediastinal mass has been completely removed. In most cases of canine autoimmune MG, once remission has occurred, recurrence of MG has been rare. Do not misinterpret a therapeutically induced decrease in AChR antibody titer and absence of clinical signs while the dog is on immunosuppressive therapy as a remission. In these cases clinical signs can return once the dosage of immunosuppressive drug is decreased. The natural course of autoimmune

MG in cats has not been determined, although it is my impression that spontaneous remissions are not as common as in dogs.

With an accurate diagnosis and early treatment, autoimmune MG is a treatable disease. Since there is a genetic predisposition to autoimmune diseases, including MG, it is recommended that myasthenic animals not be bred. Myasthenic female dogs and cats should be spayed as soon as possible after MG is under control because heat cycles and pregnancy can exacerbate active MG. Finally, vaccinations during active MG should be avoided because general immune stimulation can result in exacerbations of weakness and elevations of the AChR antibody titer (Shelton and Lindstrom, 2001; Shelton unpublished). Whether or not vaccinations can trigger MG is still an unresolved question.

CHAPTER 242

Treatment of Myopathies and Neuropathies

G. DIANE SHELTON, La Jolla, California

Neuromuscular diseases can be difficult diagnostic challenges with only a limited number of available therapeutic options. However, the most common diseases affecting muscle and peripheral nerve are treatable if a correct diagnosis is reached before irreversible pathologic changes occur. For other neuromuscular diseases, particularly the inherited myopathies and neuropathies, no therapeutic options are currently available. The old dictum of “to help, or at least to do no harm” (Hippocrates) is particularly true for this group of diseases. Treatment trials with corticosteroids before performing at least the minimum necessary diagnostics can delay or impair the ability to reach a correct diagnosis, delay initiation of specific therapies, and possibly result in irreversible contractures or even death of the animal. Further,

glucocorticoids result in a polydipsic and polyphagic animal with an increased susceptibility to infection.

The first important step is to obtain an accurate neuroanatomic localization (Glass and Kent, 2002). Neuromuscular diseases are disorders of the motor unit and as such affect neuronal cell bodies in the ventral gray matter (ventral horn) of the spinal cord (motor neuron disease), peripheral nerve (neuropathies), neuromuscular junction (disorders of neuromuscular transmission), and muscle (myopathies). A careful neurologic examination is critical. If the wrong anatomic localization is made, an incorrect diagnostic pathway would be chosen, and valuable time wasted. An incorrect diagnosis leading to inappropriate treatments could result in severe debilitation or may be life threatening.

Once clinical signs have been localized to the neuromuscular system, specific laboratory testing should be performed to reach an accurate diagnosis. A minimum database for neuromuscular diseases should include a complete blood cell count; serum chemistry profile, including creatine kinase (CK) and electrolytes; thyroid screen; urinalysis; and in most cases the acetylcholine receptor antibody titer for myasthenia gravis. Electrodiagnostic testing, including electromyography and measurement of sensory and motor nerve conduction velocity, provides important information regarding the distribution and nature of the disorder but requires specialized equipment and expertise (Cuddon, 2002). Cerebrospinal fluid analysis may be beneficial in disorders of nerve roots such as acute polyradiculoneuritis and protozoal diseases. The definitive diagnosis ultimately requires histopathologic evaluation of appropriately collected and processed muscle and peripheral nerve biopsies (Dickenson and LeCouteur, 2002). Although a specific diagnosis may not be reached in all cases, information regarding the underlying pathologic process can guide empiric therapy.

Treatment of the most common inflammatory (masticatory muscle myositis, infectious myositis) and noninflammatory (endocrine and exogenous corticosteroid-induced) myopathies, the less common noninflammatory myopathies (inherited myopathies), and the neuropathies are described in this chapter. Specific treatments for the various clinical forms of myasthenia gravis are covered in a separate chapter.

TREATMENT OF INFLAMMATORY MYOPATHIES

The inflammatory myopathies, including the immune-mediated forms (masticatory muscle myositis, polymyositis, extraocular myositis, and dermatomyositis) and those associated with infectious diseases (particularly the protozoal diseases *Toxoplasma gondii*, *Neospora caninum*, and *Hepatozoon americanum*) are relatively common in dogs. Myositis associated with neoplasia as a paraneoplastic or preneoplastic process occurs less commonly. Inflammatory myopathies occur rarely in cats as a paraneoplastic syndrome (thymoma) or associated with feline immunodeficiency virus (FIV) or feline leukemia virus (FeLV) infection. In my experience, purely immune-mediated inflammatory myopathies are uncommon in cats. Following a histologic diagnosis of an inflammatory myopathy, infectious diseases should be ruled out by serology, and screening for neoplasia should be initiated. If negative, an immune-mediated cause is likely.

Masticatory Muscle Myositis

Masticatory muscle myositis (MMM) is the most common inflammatory myopathy occurring in dogs and rarely in cats. In MMM clinical signs are restricted to the muscles of mastication without involvement of the limb muscles or other muscle groups. MMM has been recognized in most breeds of dogs and can begin as early as 3 months of age. Although MMM is a bilateral disease, clinical signs can appear unilateral, with one side more markedly

affected than the other. A particularly severe, breed-associated form of MMM has recently been identified in young cavalier King Charles spaniels. In the acute form of MMM pain and swelling of the masticatory muscles and trismus are common clinical findings. Typically the jaws cannot be opened, even under anesthesia. The cause of this inability to open the jaw in the acute stage has not been identified, and fibrosis is not obvious in muscle biopsy specimens. In the chronic stage there is atrophy of the masticatory muscles in the presence or absence of jaw pain or mobility. In end-stage MMM, atrophy is severe, and the jaw may not open greater than a couple of centimeters. In muscle biopsy specimens of end-stage disease, there is severe loss of muscle mass and replacement with fibrous tissue. MMM is very corticosteroid responsive in the acute stages and moderately so in the chronic stages. Once end-stage MMM is present, there is typically only minimal, if any, response to corticosteroids.

Because of the propensity for fibrosis, an early and accurate diagnosis is critical to a positive clinical outcome. The serum CK concentration is usually normal or only mildly elevated. Although a serologic assay currently is available for the diagnosis of MMM (demonstration of 2M antibodies by either immunohistochemistry or enzyme-linked immunosorbent assay), a biopsy of the temporalis muscle is also recommended for determination of the severity of the disease and long-term prognosis. Previous corticosteroid therapy at immunosuppressive dosages for greater than 7 to 10 days can lower antibody titers with negative results. In addition, cases with chronic, end-stage MMM can be negative for antibodies against type 2M fibers because most fibers of this type have been destroyed, removing the antigenic stimulus. If a biopsy is collected, care must be taken that the correct muscle is sampled. A common mistake is to biopsy the frontalis and not the temporalis muscle. The frontalis muscle lies directly under the skin and is not part of the masticatory muscle group. A biopsy from the frontalis muscle will not be diagnostic. Instructions for collection of an appropriate temporalis muscle biopsy specimen are given in a review of MMM by Melmed and colleagues (2004).

Following confirmation of the diagnosis of MMM, immunosuppressive therapy with prednisone should be initiated at 1 to 2 mg/kg PO every 12 hours. Treatment should be continued until the CK concentration (if elevated) has returned to the normal range, jaw mobility has returned to normal, and clinically evident jaw pain has resolved. Prednisone dosage then should be decreased gradually to the lowest alternate-day dose that will keep the dog free of clinical signs and continued for a period of at least 4 to 6 months. Relapses are common if treatment is stopped too soon. The most frequent causes of a poor clinical outcome are a delay in initiating appropriate treatment, inappropriate dosages of corticosteroids, and treatment for too short a period of time. If prednisone is poorly tolerated, other immunosuppressive drugs such as azathioprine may be used to reduce the glucocorticoid dosages. There are no controlled clinical trials detailing the efficacy of any therapeutic regimens in the treatment of canine inflammatory myopathies; thus recommendations for other agents, including cyclosporine, mycophenolate mofetil, and intravenous immunoglobulin, cannot be given.

In end-stage masticatory muscle myositis, fibrosis may be severe, and the jaw only opened a few centimeters, if that. In these cases resolution of clinical signs with corticosteroid therapy should not be expected. Maintenance of hydration and adequate nutrition may be problematic, and dogs may present with generalized muscle wasting from malnourishment related to the lack of food intake. Under no circumstances should the jaw be opened forcibly, even under sedation or anesthesia, because a jaw fracture may result. Surgical procedures such as mandibular symphysiotomy or partial mandibulectomy or hemimandibulectomy may allow tongue movement for lapping food and water.

Polymyositis

Polymyositis (PM) is an immune-mediated inflammatory myopathy that can affect all muscle groups, including the masticatory muscles; the limb muscles; and the esophageal, pharyngeal, and laryngeal muscles. PM can occur alone or as part of a generalized autoimmune disorder such as systemic lupus erythematosus. The serum CK concentration may be normal or mildly to moderately elevated, depending on the degree of muscle damage and distribution of cellular infiltrates. The 2M antibody titer is negative in most cases, even with clinical involvement of the masticatory muscles. Clinical signs may include a stiff, stilted gait; muscle atrophy; variable myalgia; regurgitation and dysphagia; and contractures in chronic cases. The diagnosis of PM is confirmed by muscle biopsy. Biopsies should be collected from more than one muscle since cellular infiltrates can have a patchy distribution and be missed on individual biopsy specimens. The large proximal limb muscles such as the vastus lateralis or biceps femoris from the pelvic limb and the triceps muscle from the thoracic limb are suggested. Once a diagnosis of an inflammatory myopathy has been histologically confirmed and infectious agents have been ruled out, immunosuppressive therapy should be initiated as for MMM. The serum CK concentration should be monitored, as well as resolution of clinical signs. Periodic screening for an underlying neoplasia is also suggested, particularly in the boxer breed (Evans, Levesque, and Shelton, 2004).

Extraocular Muscle Myositis

A focal, presumed immune-mediated inflammatory myopathy, extraocular myositis (EOM), selectively affects the extraocular muscles while sparing the masticatory and limb muscles. The clinical presentation is for bilateral exophthalmos in the acute stage or a restrictive strabismus in the chronic stage. The serum CK concentration is normal, and 2M antibodies are negative. A presumptive diagnosis of EOM can be made by clinical presentation, a negative 2M antibody test, and demonstration of swollen extraocular muscles by orbital ultrasound or magnetic resonance imaging examinations. In the acute stage resolution of clinical signs with immunosuppressive dosages of corticosteroids can be rapid. In chronic stages of EOM with fibrosis of the extraocular muscles, a favorable response to immunosuppression should not be expected.

Restrictive strabismus may result in cases with inappropriate or delayed treatments.

Dermatomyositis

Canine dermatomyositis (DM) is a familial, immune-mediated inflammatory disease of striated muscle, skin, and microvasculature in young collies, Shetland sheepdogs (shelties), and collie-crossbred dogs, but it can occur rarely in other breeds. In familial DM the clinical diagnosis is based on classic skin changes and myositis in a collie or sheltie. The onset of clinical signs is typically within the first 6 months of life. Clinical signs of myositis develop after the dermatitis and correlate approximately in severity to the degree of dermatitis. Serum CK usually is only mildly elevated. A specific diagnosis is made by skin and muscle biopsy examinations. Unlike PM, in DM the temporalis and distal limb muscles (such as the cranial tibial muscle) are more markedly affected. Treatment involves immunosuppression as in MMM and PM and symptomatic relief of skin lesions, including avoidance of sunlight, treatment of underlying pyoderma, and vitamin E (400 units q24h PO).

Inflammatory Myopathies Secondary to Infectious Agents

In my laboratory the most common cause of infectious myositis in dogs is the protozoal organism *N. caninum*. Young dogs infected with *N. caninum* can present clinically with rigid pelvic limb hyperextension, muscle atrophy resulting from myositis, and concurrent polyradiculoneuritis. In older dogs infection can cause either an inflammatory or a necrotizing myopathy. Infection with *T. gondii* is considered more common in cats, with clinical signs predominantly related to the central nervous system, respiratory system, and gastrointestinal system. Although parasite cysts may be identified in muscle biopsies from cats with neuromuscular diseases, an inflammatory myopathy with cellular reactions around the cysts is a rare finding. Although a presumptive diagnosis is based on positive immunoglobulin (Ig)G or IgM antibody titers, the definitive diagnosis depends on demonstration of the organism within muscle or other tissue by immunohistochemical or molecular methods. A combination treatment of clindamycin (10mg/kg q8h PO) and trimethoprim-sulfa (15mg/kg q12h PO) for 4 weeks has been suggested for canine neosporosis. Clindamycin (25 to 50mg/kg q8-12h) is the treatment of choice for feline toxoplasmosis.

Infection with other protozoal organisms may cause myositis in dogs, including *H. americanum* in the southern region of the United States and *Leishmania infantum* in the Mediterranean area. *Trypanosoma cruzi* may affect the myocardium and skeletal muscle of dogs in the temperate to tropical regions of the world. Although bacterial and rickettsial infectious diseases are common in the dog and cat, reports of an associated myositis are infrequent. Viral-related inflammatory myopathies are well documented in people, with retroviruses and enteroviruses most commonly implicated. Inflammatory myopathies and neuropathies have been identified in my laboratory

in FeLV- and FIV-infected cats. For more in-depth discussions of infectious causes of neuromuscular diseases and appropriate antimicrobials, references by Podell (2002) and Kent (2004) are suggested.

TREATMENT OF NONINFLAMMATORY MYOPATHIES

The largest group of treatable noninflammatory myopathies encountered in clinical practice are associated with endocrine disorders such as hypothyroidism, hyperthyroidism, and Cushing's syndrome or secondary to chronic corticosteroid therapy (the so-called *steroid myopathy*). The presence of weakness, stiffness, reluctance to move, muscle wasting, and myalgia may be the first indications of an underlying endocrine disorder in the absence of classical clinical signs.

Hypothyroid Myopathy

In newly diagnosed human hypothyroid patients, as many as 38% have clinical muscular weakness, and 80% have complaints suggestive of muscle dysfunction. The incidence of myopathic signs in canine hypothyroidism is not known but may be similar. The serum CK concentration may be normal or mildly elevated. A diagnosis of hypothyroidism can be highly suspected from histochemical evaluation of a muscle biopsy specimen and confirmed with laboratory testing, including measurement of endogenous canine thyroid-stimulating hormone and serum-free thyroxine levels by dialysis. The prognosis for recovery in hypothyroid myopathy is excellent and rapid once the dog is restored to a euthyroid state.

Hyperthyroid Myopathy

Muscle weakness and tremors may occur in feline hyperthyroidism. The serum CK may be markedly elevated, but muscle biopsies are usually normal. Resolution of clinical weakness rapidly follows correction of electrolyte abnormalities and a return to a euthyroid state. A side effect of the antithyroid drug methimazole is the development of muscle weakness approximately 2 to 4 months after initiation of therapy, with a positive acetylcholine receptor antibody titer diagnostic of acquired myasthenia gravis. Clinical signs of myasthenia resolve, and the acetylcholine receptor antibody titer returns to the normal range after cessation of the drug.

Cushing's Myopathy and Myotonia

Muscle wasting, weakness, gait abnormalities, and in some cases myotonia may be found in older dogs with Cushing's syndrome. Muscle stiffness and lameness may be an early clinical indicator of an underlying endocrinopathy. Although laboratory testing can confirm hyperadrenocorticism, type 2 fiber atrophy and excessive lipid accumulation are commonly found on histochemical examination of muscle biopsy specimens, consistent with this disease. Although not thoroughly studied, peripheral neuropathy may also be associated

with Cushing's syndrome. Clinical signs of myopathic weakness in the absence of myotonia should resolve following specific treatment. Muscle rigidity associated with myotonia is not as responsive to therapy, and deficits can persist.

Steroid Myopathy

Profound muscle weakness and atrophy can occur following chronic exogenous corticosteroid therapy in dogs. The masticatory muscles are usually the most severely affected; however, weakness and atrophy may affect the whole body musculature. As in the myopathy associated with Cushing's syndrome, prominent atrophy of type 2 fibers is a classic histologic change in muscle biopsy specimens. The fluorinated corticosteroids such as triamcinolone, betamethasone, and dexamethasone have been reported to have the most myopathic potential; thus conversion to a nonfluorinated steroid preparation with alternate-day treatment is recommended. Addition of another immunosuppressive agent that would allow lowering the dosage of corticosteroids is also suggested. Improvement usually follows but can take several weeks. Nutritional supplements may also be of benefit (see Nutritional Supplements at the end of this chapter).

Myopathies Associated with Inherited Diseases

Most of the inherited myopathies, including the muscular dystrophies (Shelton and Engvall, 2002) and other degenerative muscle diseases, occur in purebred dogs and cats less than 1 year of age. In some cases gait abnormalities and small stature may be first noticed at the time of ambulation. The breed of an affected animal is one of the most useful distinguishing diagnostic criteria of inherited diseases (Compendia of Inherited Diseases, see Fyfe, 2002). For the majority of these diseases there is no cure, and treatment options are mainly supportive. An accurate pathologic diagnosis is of particular importance to breeding programs because the goal is development of reliable molecular testing procedures for identification of carrier animals. Obtaining a specific diagnosis of these diseases is also important because inherited diseases constitute a significant proportion of diseases that cause poor quality of life or death in all breeds of dogs and cats.

TREATMENT OF PERIPHERAL NEUROPATHIES

Peripheral neuropathy remains a challenging area with regard to recognition, diagnosis, and therapy. Most often the cause of a peripheral neuropathy remains elusive despite extensive biochemical, toxicologic and electrophysiologic, histochemical, histopathologic, and electron microscopic studies of muscle and nerve biopsies. This is partly because of the limited number of ways in which peripheral nerves react to disease. Even though a specific cause may not be identified, evaluation of peripheral nerve biopsies in plastic sections can provide valuable information regarding disease severity and presence or absence of regeneration.

Neuropathies Associated With Endocrine Diseases

Neuropathies associated with endocrine diseases are relatively common with treatment based on the primary endocrinopathy. Diabetes mellitus can cause both a sensory and motor neuropathy in cats with clinical signs of a plantigrade, and in some cases palmigrade, stance. Resolution of clinical signs usually follows adequate glycemic control; however, residual deficits may occur in chronic, poorly controlled cats. Weakness and muscle atrophy consistent with neuropathy may also occur in diabetic dogs, although most cases are complicated by hypothyroidism or Cushing's syndrome. Hypothyroidism in dogs may be associated with peripheral neuropathy, although the mechanisms are poorly understood. Following hormone replacement, gradual improvement in neurologic signs should result; however, this may take several months. Neuropathy is also a rare complication of pancreatic β -cell (adeno)carcinoma. Although clinical signs of neuropathy may improve following surgical intervention, the prognosis for complete remission from an insulinoma and the accompanying peripheral neuropathy is poor.

Nutritional and Toxic Causes of Polyneuropathy

Although nutritional and toxic causes of polyneuropathy are not common or well documented in veterinary medicine, they may be treatable; thus the owner should be questioned carefully about diet, dietary supplements, and any previous drug therapies. Review of the health history and a thorough physical examination should also be performed for identification of an underlying gastrointestinal disease that could impair absorption. In my laboratory neuropathies have been identified in dogs associated with a several-year history of a raw fish diet and vitamin B deficiency (<http://vetneuromuscular.ucsd.edu>, March 2001 Case of the Month), chronic treatment with metronidazole (March 2002 Case of the Month), and a several-week history of nitrofurantoin treatment for chronic urinary tract infections (September 2001 Case of the Month). Although not fully documented in the veterinary literature, vitamin B₁ deficiency and toxic neuropathies associated with metronidazole and nitrofurantoin treatments are described in the human literature.

Neuropathies and Neoplastic Disorders

Lymphoma is the most common tumor of nonneural origin that affects the peripheral nervous system (PNS). Neoplastic cells, particularly in cats, can infiltrate the nerve and nerve roots, resulting in clinical signs of polyneuropathy in addition to signs of multicentric lymphoma. The diagnosis is confirmed by electrodiagnostic testing and demonstration of neoplastic cells within a peripheral nerve biopsy. Chemotherapy should be aimed at treating the underlying neoplasia. Chemotherapeutic drugs such as vincristine and cisplatin used in the treatment of lymphoma and solid tumors respectively may themselves cause peripheral neuropathy. Malignant

peripheral nerve sheath tumors are the most common primary nerve tumor affecting the PNS. Although surgical excision and amputation are described, the prognosis is poor because recurrence is common with extension into the vertebral canal or thorax.

Inflammatory and Immune-Mediated Neuropathies

Organisms such as *T. gondii* and *N. caninum* can cause inflammatory and degenerative changes in peripheral nerves and nerve roots, as well as muscle. Diagnosis and treatment are as stated previously. Acute canine polyradiculoneuritis (coonhound paralysis, ACP) is one of the most commonly recognized canine peripheral neuropathies, characterized by lymphocytic radiculitis and demyelination of the ventral, and less commonly dorsal, nerve roots. Ascending tetraparesis or tetraplegia occurring over 1 to 2 days is characteristic of this disease. Treatment is supportive and includes physical therapy and bladder evacuation. Corticosteroids should not be used in dogs with ACP because they do not improve clinical signs or shorten the course of the disease and may in fact exacerbate the disease and reduce survival rate.

Chronic (relapsing) demyelinating polyradiculoneuritis refers to a group of chronic, progressive, or relapsing motor and sensory peripheral neuropathies that are associated with inflammatory changes in the spinal nerve roots, as well as in the cranial nerves and more peripheral regions of appendicular nerves. An autoimmune attack against peripheral nerve myelin is suspected. A definitive diagnosis of the pathologic nature of the neuropathy and the severity and distribution is achieved by electrophysiologic evaluation and muscle and peripheral nerve biopsies. Because of the suspected immune-mediated nature of this group of neuropathies, immunosuppression with prednisone (1 to 1.5 mg/kg q12h) has been recommended. Even with therapy, the long-term prognosis is guarded since relapses are common and the disease is progressive over months to years.

Cellular infiltrates may invade the most distal intramuscular nerve branches and be evident within muscle biopsies, particularly in cats. Although studies of this disorder are still in progress, this neuropathy appears to be steroid responsive, with complete resolution of clinical signs following corticosteroid therapy.

Chronic Axonal Degeneration

Chronic, slowly progressive, idiopathic axonal degeneration affects middle-age-to-older large-breed dogs. Clinical presentation is for progressive paraparesis or tetraparesis. Laryngeal paralysis may be an early clinical sign of a generalized peripheral neuropathy. A typical scenario is onset of peripheral weakness several months following laryngeal tie-back surgery, or weakness and atrophy of the distal limb muscles may be present at the time of surgery. All diagnostic evaluations (biochemical, endocrine, or metabolic screening, as well as radiography and ultrasonography) are normal. Diagnosis is based on electrodiagnostic testing and muscle and peripheral nerve biopsy. Peripheral nerve biopsy is of particular importance in

these cases because the extent of nerve fiber loss or endoneurial fibrosis and the presence or absence of regeneration are important in determining the course of disease and long-term prognosis. At this time no proven successful therapeutic options are available. Physical therapy and nutritional supplements are suggested in the following paragraphs.

ADJUNCTIVE THERAPY

Unless indicated by obvious cellular infiltrates within muscle and peripheral nerve biopsies or an inflammatory cerebrospinal fluid, treatment trials with glucocorticoids in the absence of a specific diagnosis can do more harm than good. Corticosteroids are catabolic in nature and thus could worsen muscle mass and weakness. Suggested supportive therapies for myopathies or neuropathies without a specific underlying cause include physical therapy and nutritional supplementation.

Physical Therapy

Inactivity can further diminish muscle mass in cases of neuromuscular diseases, and weakness may be aggravated by contractures. Mild exercise may prevent some of the atrophy induced by glucocorticoid treatments or hyperadrenocorticism; thus walking should be encouraged. Passive range-of-motion exercises positively influence reinnervation and the sprouting process in denervated muscle and may be of therapeutic value.

Nutritional Supplements

Nutritional supplements may be beneficial when a specific diagnosis is not identified or used in conjunction with corticosteroids in inflammatory myopathies or neuropathies to counteract the side effects of additional muscle atrophy and weakness. Although controlled studies have not yet been performed, various vitamins and nutritional supplements have been advocated for patients with neuromuscular diseases. The goal is to increase muscle mass and strength by anabolic agents, exercise, and physical therapy rather than worsen muscle weakness and atrophy by inactivity and harmful drugs. I recommend

L-carnitine (100mg/kg q24h), coenzyme Q₁₀ (4mg/kg q24h), and supplementation with B vitamins. This therapy should not be harmful and may help improve muscle strength. Several different muscle diseases are associated with low muscle carnitine concentrations (Shelton, unpublished data), and dramatic improvement may result in some cases. The owners should be informed that in most cases this is not a cure, but, most important, it cannot be harmful. The metabolic benefits of L-carnitine include transportation of fatty acids into the mitochondria for energy generation and the urinary excretion of abnormal metabolites. Coenzyme Q₁₀ functions as a cofactor in several enzyme systems related to energy conversion (electron transport) and is a vital catalyst to energy production at the cellular level. It is also a free radical scavenger. For degenerative peripheral nerve diseases, acetyl-L-carnitine may be more beneficial than the L-carnitine form. Clearly controlled clinical trials are necessary to document the efficacy of these treatments of neuromuscular diseases.

Treatment of Supraspinatus Tendon Disorders in Dogs

BOEL A. FRANSSON, *Pullman, Washington*

Forelimb lameness in adult dogs is generally considered one of the most frustrating orthopedic problems facing veterinarians. Well-described disorders in small animal orthopedics such as biceps tendonitis or nerve sheath tumors may be difficult to diagnose. Add to that the likelihood that many causes of forelimb lameness remain undescribed in veterinary medicine, and it is understandable that inability to reach a final diagnosis in cases with forelimb lameness is more common than in hind limb lameness.

Successful treatment of forelimb lameness in dogs requires an accurate diagnosis of the underlying problem. Traditionally lameness elicited from nonosseous disorders of the extraarticular shoulder region have been particularly difficult to diagnose since radiographic examination is an insensitive detector of soft-tissue abnormalities and direct visualization via arthroscopy is not possible. Increasing access to more advanced imaging technology is expanding our abilities to recognize disorders of structures such as the supraspinatus tendon. The main abnormality of the supraspinatus tendon previously recognized has been mineralization (calcification) of the tendon insertion. Magnetic resonance imaging (MRI) provides high resolution delineation of soft tissues in three dimensions. In addition, by using several image sequences, MRI may provide some information about the characteristics of abnormalities seen (e.g., fluid content, fat content, vascular supply). With MRI becoming increasingly available to the practicing clinician, it is reasonable to believe that the veterinary community will see emerging diagnoses that will require novel treatments. Overuse tendinopathy (tendinosis) of the supraspinatus tendon is one such recently described diagnosis that has been demonstrated to occur in dogs. Diagnosis and management of the two supraspinatus disorders described to date in dogs are discussed.

SUPRASPINATOUS TENDON ANATOMY

The supraspinatus muscle in dogs arises from and is located in the supraspinous fossa of the scapula. The muscle curves around the neck of the scapula and ends in a short, approximately 9-mm thick (in dogs 19 to 28 kg) tendon on the craniomedial aspect of the major tubercle of the humerus. The supraspinatus muscle is innervated by the suprascapular nerve, and the action of this musculotendinous unit is to extend the shoulder joint and advance the limb forward. The supraspinatus tendon of insertion lies immediately craniomedial to the bicipital

tendon in the intertubercular groove (Fig. 243-1). These two tendons are separated by the bicipital tendon sheath (an extension of the shoulder joint capsule) and, at the distal half of the greater tubercle, also the transverse humeral ligament.

An area of diminished or absent vascularization ("critical zone") is located in the part of the supraspinatus tendon immediately adjacent to the greater tubercle. This hypovascularization, which is also seen in humans, has been suggested to be a cause for supraspinatus tendon degeneration. Similar to that of most normal tendons, the collagen composition of the supraspinatus tendon consists primarily of type I collagen. However, in the insertion area of the canine supraspinatus tendon a significant amount of type III collagen has been demonstrated. Type III collagen is usually part of the early phase of wound repair and tends to be replaced with type I as the mechanical strength of the wound returns to normal. This differential collagen composition of the supraspinatus tendon may indicate that the insertion region is subjected to different stress than other tendons and may contribute to formation of degenerative changes.

SUPRASPINATUS TENDON MINERALIZATION

A calcifying tendinopathy of the supraspinatus tendon was first described in dogs by Flo and Middleton (1990). However, this abnormality may also represent an incidental finding in dogs, and a major difficulty in the diagnostic workup of this disorder is to rule out any other possible source of lameness.

Histopathologic examination of tissue resected in dogs with mineralization of supraspinatus tendon reveals fibrocartilaginous metaplasia with dystrophic mineralization of the tendon. Collagen bundles are often arranged haphazardly, and collagen fibers are separated by a myxomatous matrix, which can be verified by Alcian blue staining. There are no or minimal inflammatory changes.

Medium- to large-breed adult dogs are affected most commonly, and the lameness tends to show an insidious onset resulting in an intermittent or progressive weight-bearing forelimb lameness worsening during or after exercise. The lameness has often been present for several months by the time of diagnosis.

On physical examination many dogs show pain or resistance to movement during shoulder flexion. Less often pain is elicited by deep palpation with pressure focused

Fig. 243-1 Cranial-to-caudal view of the left shoulder. The pectoral muscle insertion is transected to expose the musculo-tendinous junction of the biceps. *BT*, Biceps tendon; *GT*, greater tubercle (laterally); *LT*, lesser tubercle (medially); *SGT*, supraglenoid tubercle; *STI*, the center of the supraspinatus tendon insertion; *THL*, transverse humeral ligament.

over the craniomedial aspect of the greater tubercle. In some cases pain cannot be elicited by shoulder manipulation or digital palpation of the tendon. In general, the mineralizations are not large enough to be palpated.

During physical examination attention must be paid to any other possible source of lameness. Shoulder or elbow joint dysplasia or osteoarthritis, osteosarcoma of the proximal humerus, bicipital tenosynovitis, cervical intervertebral disk disease, and brachial plexus nerve sheath tumors, among other disorders, may all show lameness with similar characteristics as elicited from supraspinatus tendon mineralization. Bicipital tendon pain elicited by digital palpation in dogs with concurrent mineralization of the supraspinatus tendon may present a problem.

Diagnosis of supraspinatus mineralization can be confirmed by radiographic examination, but one must bear in mind that radiographic diagnosis does not confirm that lameness stems from this abnormality. A lateral view of the shoulder joint often shows the mineralization (Fig. 243-2). However, the mineralization might be obscure as a result of superimposition of the greater tubercle. Commonly bilateral radiographic changes are seen despite unilateral lameness.

To demonstrate that the mineralization is located in the plane of the supraspinatus tendon, a cranioproximal to craniodistal radiographic view (Fig. 243-3) of the shoulder joint is necessary. This view is obtained by placing the dog in sternal recumbency with the cassette placed on top of the forearm with the elbow flexed. The radiographic tube is positioned in a proximal-to-distal orientation directly over the scapulohumeral joint. To facilitate positioning of the tube the head of the dog has to be pulled to the contralateral side. A traditional craniocaudal projection usually adds little information and is not necessary.

Fig. 243-2 Lateral view of the shoulder of a dog with mineralization of the supraspinatus tendon of insertion. The mineralization is visible in the tendon insertion immediately cranial to the greater tubercle.

With MRI there is often a hyperintense signal within the tendon on T2-weighted and fat-suppressed images, indicating increased fluid content in the part of the biceps tendon that is immediately adjacent to the mineralization in the supraspinatus tendon. We suspect that the mineralized supraspinatus tendon may cause mechanical irritation of the bicipital tendon sheath or tendon. However, ruling out bicipital tenosynovitis as the primary source of the lameness in these cases may prove difficult. Careful palpation of the intertubercular groove, with digital pressure applied on the biceps tendon while avoiding placing pressure on the slightly more laterally located

Fig. 243-3 Cranioproximal-to-craniodistal radiographic view of the canine shoulder in Fig. 243-2. The biceps tendon is located in the intertubercular groove between the greater (GT) and lesser (LT) tubercles, but it is not visible on the radiograph. The mineralizations medial to the greater tubercle were all located in the supraspinatus tendon in this case.

supraspinatus tendon, may distinguish pain elicited from the biceps tendon but will not reveal which of the problems is the primary cause of pain. Direct visualization of the biceps tendon through arthroscopy can help rule out primary biceps tenosynovitis.

Treatment

Rest and nonsteroidal antiinflammatory drugs (NSAIDs) have been reported to improve the lameness in a small number of dogs (Laitinen and Flo, 2000). These dogs had lameness of short duration (2 months or less), and the recovery time ranged from 2 to 8 weeks.

In dogs that are unresponsive to conservative management, surgery has been reported to improve lameness dramatically. Surgery consists of a 4- to 7-cm long cranial skin incision centered over the greater tubercle. The deeper dissection involves the brachiocephalic muscle, the fibers of which are divided longitudinally to gain access to the supraspinatus tendon of insertion. Longitudinal incisions in the tendon reveal the mineralized material that is removed. Closure is made in layers with absorbable or nonabsorbable suture material. Time to recovery after surgery seems to be highly variable with a median of 8 to 12 weeks. However, some dogs require 24 weeks before the end result of the treatment is reached.

Extracorporeal shock wave therapy has been reported to improve lameness associated with supraspinatus mineralization in two dogs (Danova and Muir, 2003). The single noninvasive treatment was carried out under sedation only. The long-term outcome of this novel treatment is unknown because the follow ups were very short (3 to 7 weeks).

SUPRASPINATUS TENDINOSIS

Chronic degenerative tendinopathy, tendinosis, is commonly seen in the common calcaneal (Achilles), patellar, and supraspinatus tendons in humans. Although the etiology is unknown, overuse injury has been suggested and supported by findings of experimental animal models. The disorder is characterized by persistent activity-related pain and swelling localized to the affected tendon.

A disorder of the supraspinatus tendon in a dog very similar to human tendinosis was recently reported from our institution, and this abnormality has subsequently been demonstrated in several other cases at our hospital and at other institutions. Histopathologic changes have shown disorganized collagen fibers that lack reflectivity under polarized light and a prominent myxomatous degeneration without calcification or inflammatory changes. It seems likely that the lack of radiographic changes associated with this disorder has prevented confirmation of the diagnosis previously. With the current, more frequent use of advanced imaging, soft-tissue changes such as tendinosis are easier to demonstrate.

Signalment and clinical features of dogs with tendinosis are strikingly similar to those of supraspinatus mineralization. Adult medium- to large-breed dogs, usually with a very active lifestyle, appear to be affected most frequently. In a majority of cases the lameness has been long-standing, intermittent to continuous, and nonresponsive

to NSAID treatment. Despite the fact that most dogs show bilateral changes, the lameness is usually unilateral. Palpation of the tendon does not elicit a strong pain response, but some discomfort or pain is usually noted on shoulder flexion.

Application of MRI has aided diagnosis. The most consistent finding is an increased mass of the supraspinatus tendon of insertion, with hyperintense signal on T2-weighted and short tau inversion recovery (STIR) images. A curious finding in many dogs is that the increased mass of the supraspinatus tendon appears to displace the biceps tendon medially. Sometimes this is associated with a focal increase in signal intensity on T2-weighted and STIR images in the biceps tendon located at the point of maximum contact between the tendons. We suspect that the increased mass of the supraspinatus tendon mechanically interferes with the biceps tendon and its related structures, leading to focal irritation or degeneration and possibly pain. The chronic irritation may lead to secondary changes in the biceps tendon itself or in structures such as the transverse humeral ligament, which restricts the medial translation of the biceps tendon induced by the increased supraspinatus tendon volume. Definitive diagnosis is confirmed by histopathologic examination.

Treatment

Long-term outcome of surgery has only been reported in one dog at present. After surgical resection of the degenerated part of the tendon and thus decompression of the biceps tendon, the dog rapidly improved, and the lameness of 5 months' duration remained resolved 2 years after surgery. Further data are needed to predict to refine the prognosis and outcomes for this disorder.

In humans continuous rest of 3 to 6 months has been suggested to combat collagen breakdown and promote recovery from chronic tendinosis. Surgery has been considered a last resort for humans with tendinosis. However, secondary changes in the biceps tendon have not been noted in humans, probably because of the difference in anatomy, leading to a lack of interference between the two tendons.

At our institution surgery is the recommended treatment in dogs to prevent degeneration of the biceps tendon and also to establish diagnosis. At the time of surgical exploration of the supraspinatus tendon, arthroscopy of the ipsilateral shoulder joint is generally performed to confirm that coinciding shoulder disorders are not present. If the transverse humeral ligament appears thickened or fibrotic based on MRI and direct visual examination, transection of this structure is considered in an attempt to minimize irritation and/or ischemia of the biceps tendon.

Histopathologic examination has not demonstrated inflammatory changes associated with this disorder. Therefore antiinflammatory NSAIDs are prescribed only to minimize the inflammation and discomfort associated with surgery (i.e., 5 to 7 days). There appears to be no advantage in using corticosteroids locally or systemically for this disorder; in humans, corticosteroids are contraindicated because they inhibit collagen repair. Adjunctive

therapy that has included laser treatment, high-voltage galvanic stimulation, application of load-decreasing devices, and strengthening exercises have been described for supraspinatus tendinosis in affected people.

Are the Two Disorders One?

Signalment and clinical presentation in both of the disorders described in this chapter are strikingly similar. In addition, the location of pathologic changes and the histopathologic findings are very similar, with the only notable difference being lack of mineralization in cases with tendinosis. It is possible that both disorders represent the same disease process, with an individual variation of the propensity for hydroxyapatite crystal deposition leading to variable mineralization. Hereditary, traumatic, metabolic, neurologic, degenerative, and vascular factors have all been suggested as underlying reasons for hydroxyapatite crystal deposition in human paraarticular tissues. Future research, including larger clinical studies, may

shed more light on the pathophysiology of canine degenerative disorders of the supraspinatus tendon.

CHAPTER 244

Medical Treatment of Coxofemoral Joint Disease

DENIS J. MARCELLIN-LITTLE, *Raleigh, North Carolina*

The diseases of the hip joint in dogs include hip dysplasia, Legg-Perthes disease, and osteoarthritis (OA). Canine hip dysplasia is a ubiquitous disease affecting most if not all dog breeds. Hip dysplasia is considered to be the most common orthopedic disease. In two recent scientific reports hip dysplasia was present in more than 40% of golden retrievers, Labrador retrievers, or rottweilers (Paster et al., 2005; Smith et al., 2006). Although canine hip dysplasia has been the core of several hundred scientific publications, the majority of these publications are linked to the genetic basis of the disease and its surgical management. Only a handful of articles cover the conservative management of the disease, with, to our knowledge, only one study having assessed prospectively its long-term clinical signs and progression (Smith et al., 2006). As a consequence, most of the recommendations included in this article are extrapolated from anecdotal reports, clinical experience, research models, or clinical studies in humans.

Development of OA in the canine hip joint most often results from hip dysplasia, but may also result from fractures of the acetabulum, femoral head, or femoral neck. Most acetabular fractures result from motor vehicle accidents. OA was present in 9 of 10 (90%) and 11 of 14 (79%) hip joints after acetabular fracture repair in two reports by Anson (1988) and Lewis (1989). Another report identified OA in all 15 caudal acetabular fractures managed without surgery (Boudrieau and Kleine, 1988). Most femoral head fractures are physeal fractures of the capital physis of the femur. Their surgical repair may lead to hip OA.

Hip dysplasia is an inherited developmental condition involving a lack of fit between the femoral head and acetabulum, invariably leading to OA (Lust, 1997). When present, hip dysplasia is most often bilateral. The clinical signs of hip dysplasia are most often described as acute in skeletally immature or young adult dogs and chronic in older dogs. Acute clinical signs tend to reflect acute pain: a potentially severe, often unilateral lameness. They

generally appear between 4 and 8 months of age. Affected dogs may show a reluctance to perform propulsive activities, including jumping, climbing steps or stairs, galloping, or walking for extended periods of time; or they may exhibit behavioral changes, including reluctance to play, introversion, or showing aggressive tendencies. The chronic clinical signs of hip dysplasia include exercise intolerance, a reluctance to jump up and climb steps or stairs, and a bunny-hopping gait anomaly at a gallop.

Surprisingly, little has been written about the specific body changes present in dogs with chronic hip dysplasia (Barr et al., 1987; Johnston, 1992; Remedios and Fries, 1995; Read, 2000). Dogs with hip dysplasia have pain arising from their femoral and acetabular joint surfaces and hip joint capsule, particularly when moving at higher speed and during extension of the hip joints. Over time dysplastic dogs tend to lose hip extension but do not appear to lose hip flexion. Dogs lose joint motion because of the development of large osteophytes and enthesophytes on the caudal and ventral aspects of the acetabulum and on the femoral neck and caudal aspect of the greater trochanter. Pain response during hip joint flexion, subjectively, is very unusual and may be the consequence of other problems such as a septic arthritis, a bone tumor, or another problem. Most dysplastic dogs lose muscle mass in their pelvic limbs. Some may displace their center of gravity forward by flexing their spine, shoulder, and elbow joints. Overall the clinical signs of hip dysplasia vary widely among affected dogs. Some have very discrete signs that may appear after long periods of strenuous exercise; others have a severe disability and are unable to trot, gallop, or jump.

Little is known about the relationship of specific aspects of hip joint disease (i.e., dorsal subluxation, dorsal luxation, cartilage wear, dorsal rim wear, joint capsule thickening, osteophyte production, and the presence of joint mice) and the type and severity of clinical signs. Surprisingly, dorsal hip luxation is sometimes diagnosed in dogs with relatively mild clinical signs of dysplasia. Other dogs without luxation have significantly more hip pain. Also surprisingly, the size and location of osteophytes do not appear to correlate well with clinical signs of hip dysplasia. Clinical signs also appear to be linked to dog size: larger dogs are less likely to be nonweight bearing or to present with severe limb disuse than smaller dogs.

The management of hip dysplasia may involve surgery. Surgery may be performed early in life to positively influence the developing pelvis and hip joint or later in life to limit the pain and disability resulting from hip OA. Many patients with hip dysplasia are managed conservatively without surgery. Because hip dysplasia is a lifelong, progressive disease that impacts the daily activities of affected animals, it is critical for veterinarians to establish long-term, sustainable management programs for their patients. These programs must also be multifaceted because managing OA involves several objectives: decreasing pain, maintaining cardiovascular fitness, maintaining or increasing muscle strength, restoring or maintaining joint mobility, maintaining proprioception, optimizing weight, and adapting the home and environment.

OPTIMIZING SKELETAL DEVELOPMENT

Screening for Hip Laxity and Subluxation

Because of the high incidence of hip dysplasia in many breeds, particularly in large breeds with thick subcutaneous tissues and relatively modest muscle development (e.g., Saint Bernard, Bernese mountain dog, and mastiffs), it is indicated to screen breeds at risk for the presence of predisposing factors to hip dysplasia early in life. Since hip subluxation appears to be the key predisposing factor to dysplasia, the hip joints should be screened for the presence of hip subluxation at a young age. Hip subluxation may be reliably detected at 16 weeks of age using stress (distraction) radiography and, to a lesser extent, palpation. Palpation may be performed with the dog awake or under sedation. Palpation is ideally performed with the patient in lateral recumbency with the hip joint held in a position similar to a standing position. A flat hand may be placed on the proximal and medial aspect of the thigh, and abaxial pressure may be placed on that thigh. Abaxial displacement of the femur in relation to the pelvis may be palpated by feeling the relative position of the greater trochanter and the ischial tuberosity (Bardens sign). Also on palpation, preferably with the dog in dorsal recumbency, a reduction of the femoral head in the acetabulum may be felt by placing the hip in a position similar to a standing position and slowly abducting the femur. If the hip joint is subluxated initially and returns in a reduced position, a clunking sound will be heard during hip reduction (Ortolani sign). The angle at which the Ortolani sign occurs is a reflection of potential wear of the dorsal acetabular rim; more severe wear is expected with higher angles.

When the femur is slowly adducted toward a standing position, a more subtle displacement may be felt as the hip joint subluxates again (Barlow sign).

As for the reduction angles, higher subluxation angles indicate more severe dorsal rim wear. The feel of the Ortolani sign and subluxation may be smooth and crisp in hip joints with minor damage or rough and subtle in hip joints with cartilage and dorsal acetabular rim damage. We often see 20- to 40-degree differences between the angle of reduction and the angle of subluxation. A positive angle indicates abduction; a negative angle indicates adduction. Dogs with hip laxity without dorsal rim damage often have angles of reduction around 20 degrees and angles of subluxation around -20 degrees. Dogs with severe dorsal rim damage often have angles of reduction around 45 degrees and angles of subluxation around 20 degrees. Subjectively it appears that higher reduction and subluxation angles are more a factor of dorsal rim wear than of pure joint laxity. A dog with low reduction and negative subluxation angles may be able to maintain its hip joint reduced or intermittently reduce its hip joint during locomotion by slightly abducting its femur, in the same way that a dog with patellar luxation may relocate its patella. This may be observed at a walk or trot. With time, most dogs with hip subluxation will develop dorsal rim wear, and the positive Ortolani sign will disappear because of permanent dorsal hip subluxation. The age at which the Ortolani sign disappears in dysplastic dogs

has not been scientifically assessed to our knowledge. Clinically most Ortolani signs disappear by 18 months of age. Most but not all dogs with positive Ortolani signs will develop hip dysplasia during the first few years of their adult life.

The laxity present in hip joints may be measured reliably at 16 weeks of age and later using stress radiography. Although multiple radiographic assessment methods are available, the PennHIP method is the most accurate method used to assess the presence of hip laxity. A PennHIP evaluation includes a distraction view that quantifies the degree of abaxial displacement of the femoral head in relation to the acetabulum during a maneuver resembling the Bardens sign. Reliable hip distraction is achieved using foam-covered adjustable acrylic tubes. The distraction index (DI) is the distance separating the centers of the acetabulum and femoral head during distraction divided by the radius of the femoral head. Dogs with low DI (<0.30) are very unlikely to develop hip dysplasia. Dogs with higher DI (>0.70) are very likely to develop hip dysplasia. Some dog breeds are more laxity tolerant than other breeds; for example, in a study involving 3729 German shepherds and 6278 Labrador retrievers older than 24 months, the likelihood of having hip OA in dogs with a DI of 0.6 was approximately 58% for German shepherds compared to approximately 16% for Labrador retrievers. This shows that joint laxity is not the sole factor leading to the development of hip arthritis and suggests that differences in anatomy and joint mechanics play an important role in the development of hip dysplasia (Smith et al., 2001). In a report assessing 459 clinically normal dogs, palpation was at best moderately correlated with radiographic measures of joint laxity, indicating the need to combine palpation with stress radiography when screening dogs for hip laxity (Puerto et al., 1999).

Optimizing Growth

Within litters both the severity and rate of progression of hip dysplasia are increased in larger dogs compared to smaller dogs and in dogs receiving calcium or phosphorus oversupplementation. Also, severity and rate of progression of hip dysplasia are decreased in dogs with slight (i.e., 25%) caloric restrictions during growth compared to dogs eating *ad libitum*. Protein amounts in the food do not appear to impact skeletal growth directly but may impact it indirectly if skeletally immature dogs are fed a low-protein diet; the need to eat more food to fulfill their protein needs will increase their energy/caloric consumption, increasing their risk of developing hip dysplasia.

Twice-weekly administration of polysulfated glycosaminoglycans between 6 weeks and 8 months of age has led to less subluxation and indicated a trend toward less cartilage damage for pups predisposed to the development of hip dysplasia in one prospective study (Lust et al., 1992).

Minimizing Joint Pain

When hip dysplasia is detected in an adult dog, conservative management options are aimed at minimizing pain; optimizing living conditions; maintaining cardiovascular fitness, muscular strength and endurance, and joint

motion; and, if deemed necessary, providing ambulation assistance.

Minimizing joint pain is a major aspect of the conservative management of hip dysplasia. It is achieved by optimizing the living conditions of patients, tailoring their activities, encouraging weight loss, giving pain medications, and food supplementation. Little is known about the impact of living conditions on the clinical signs of hip dysplasia in dogs. The general clinical signs of OA in humans include periods of relative calm and periods of sudden exacerbation of signs (flares or flare-ups). With time flares become more frequent and more severe and tend to last longer. In dogs with hip dysplasia, flares seem to result from excessive activity in unfit dogs (the weekend warrior syndrome) or from events that place excessive stress on arthritic joints such as jumping or stepping in a hole. Flares may last several hours to several weeks. Determining if an arthritic joint has flared is an important part of the initial assessment of all OA patients because treatment goals and methods differ. A flare is likely to be present in dogs with clinical signs that are significantly more severe than they were in preceding weeks. It is very common to first examine arthritic dogs at the time of a flare because the sudden increase in severity of their clinical signs gives owners a clear incentive for presentation to a veterinarian. A sudden loss of performance (e.g., inability to climb steps or into a motor vehicle, exercise intolerance) is often the result of a chronic, progressive loss of strength and fitness secondary to OA and aging, a change in the status of an arthritic joint (i.e., a subluxated hip joint becomes luxated), or the presence of a flare. Irreversible decisions such as surgery or euthanasia are ill-advised during flares because patients may appear overly affected and often are demonstrating dramatically decreased mobility. Instead the focus should be on comprehensive pain management and rest. Between flares owners should avoid strenuous activities that lead to an increase in clinical signs of OA and promote activities that do not. Potentially strenuous activities include jumping up, chasing, retrieving, and playing with other dogs. Unfortunately these activities are often chosen by owners because dogs love them, because they are easy to perform, and because they require minimal to no owner participation.

Changes in temperature (cold wave), humidity, and barometric pressure (decrease in pressure) have been reported to influence the pain perceived from arthritic joints in humans. To minimize the potential impact of weather conditions on arthritic dogs, it may be beneficial to make sure that they are housed in a weather-controlled environment. Minimizing slipping and falling may benefit them as well and may be achieved by improving the traction of walking surfaces and avoiding activities requiring sudden changes in direction or speed. In dogs with severe OA ambulation assistance may be provided by a step-in sling or harness. Neoprene harnesses with hook and loop fasteners are popular because they are ergonomic, relatively soft, durable, and washable. For large, heavy, or independent dogs with locomotion difficulties, an ambulation cart may provide effective ambulation assistance. In most instances, when pain and weakness are limited to the pelvic region, a two-wheel cart is used.

When dogs have problems involving all four limbs, a four-wheel (quad) cart may be used. The cart supports the pelvic region during outdoor activity. Some, but not all dogs, learn to negotiate door frames and may use their cart indoors. Because arthritic dogs maintain normal motor function during activity, we have the subjective impression that neoprene slings may be the optimal support material for the pelvis of arthritic dogs. On the other hand, neurologically compromised dogs that have abnormal pelvic motor function may ambulate more effectively with rigid pelvic resting surfaces (foam-covered aluminum rings).

Without appropriate pain relief, strengthening and maintaining joint mobility is rarely accomplished. Relief is achieved by interfering with the *peripheral* (tissue inflammation and damage) and *central* (neuropathic; involving the central nervous system) aspects of pain. Managing the peripheral component of OA pain hinges on pharmacologic treatment, specifically nonsteroidal antiinflammatory drugs (NSAIDs) that decrease the transduction and transmission of noxious stimuli in affected tissues and peripheral nerves. NSAID administration in dogs may lead to dramatic improvement in limb use and overall function. Several NSAIDs are approved for chronic use in the United States and other countries. Several scientific reports, often used as supporting studies for drug approval, have shown that NSAID administration has led to an increase in the peak vertical force and vertical impulse placed on the pelvic limbs of arthritic dogs. There is no published peer-reviewed study that has compared the commercially available NSAIDs using a blinded, prospective, randomized, crossover design. Despite the absence of such data, it is clear that NSAIDs have a significant positive impact on the comfort and mobility of dysplastic dogs. The relative occurrence and seriousness of side effects after administration of various NSAIDs in dogs has not been evaluated scientifically. All NSAIDs have infrequent but potentially serious side effects and should be used cautiously in dogs, particularly in patients with compromised liver or renal functions, hypovolemic patients, and patients with gastrointestinal disease or congestive heart failure. This is particularly relevant since many arthritic dogs show an increase in clinical signs later in life when liver, renal, cardiovascular, and gastrointestinal problems are more likely to be present. Periodic enzymatic and liver function screening is recommended in dogs receiving NSAIDs. Although there is no consensus on the frequency of these screenings, it seems reasonable to perform them before the administration of NSAIDs, after a few weeks of NSAID administration, and if clinical signs arise. As in all forms of chronic pain, peripheral sensitization and spinal cord wind-up occur with chronic hip dysplasia. Multimodal drug and nondrug therapy has been recommended to manage this chronic pain. This includes the use of pain medications that are adjunctive or alternative to NSAIDs. Adjunctive drugs may be considered for NSAID-intolerant dogs or for dogs with clinical signs that are only partially improved during NSAID therapy. The scientific information supporting these alternative medications is scant, but clinical research in that area is active. Tramadol, a synthetic morphine analog, is seemingly the most commonly used adjunctive drug for

chronic hip pain. Other emerging drugs used in the multimodal drug management of OA include the γ -aminobutyric acid analog drug gabapentin and the antiviral drug amantadine (Lascelles et al., 2008).

In addition, subjectively, dogs with severe arthritic flares may benefit from continuous-rate intravenous infusion of a combination of an α -2 adrenergic agonist (medetomidine), sodium channel blockers (lidocaine and *N*-methyl *D*-aspartate receptor antagonists (ketamine, amantadine).

Nutritional supplementation has long been used to potentially decrease the pain associated with arthritic pain in humans, most often through the use of compounded herbs and vegetables such as in traditional Chinese and Indian Ayurvedic medicine. More than 30 herbs or compounds have shown some level of pain relief in prospective randomized trials involving humans with OA. In Western medicine the attention has focused mainly on the use of glucosamine, chondroitin sulphate, and polyunsaturated (omega-3) fatty acids for the management of arthritic joint pain, with several well-structured studies documenting their benefits. By comparison, little is known about the benefits of nutritional supplements in arthritic dogs. However, several clinical trials have documented the benefits of a diet containing glucosamine, chondroitin, and eicosapentaenoic acid (EPA), an omega-3 fatty acid, on the clinical signs of hip dysplasia in dogs. Several reports have documented the anti-inflammatory or anticatabolic effects of omega-3 fatty acids, glucosamine, or chondroitin on human and canine chondrocytes *in vitro*. Increasing the nutritional intake of EPA has been shown to decrease osteoarthritic pain, probably by decreasing arachidonic acid concentrations and increasing EPA concentrations in the cell membranes of canine chondrocytes. Green-lipped mussel supplements also appear to alleviate the clinical signs of OA in dogs. Our current body of knowledge suggests that the most reasonable drug administration and nutritional plans for arthritic dogs would be to keep them free of clinical signs by using NSAIDs, omega-3 fatty acids, glucosamine, and chondroitin sulphate and by potentially adding adjunctive drugs (if deemed necessary based on the clinical signs or as an alternative to NSAIDs if clinical signs of intolerance are present).

Nonpharmacologic, antiinflammatory options for peripheral pain management include cold therapy (icing) and massage. Icing provides direct pain relief by decreasing nerve conduction velocity. It also provides secondary pain relief by decreasing edema (itself a source of pain) and decreasing the overactivity of catabolic enzymes in osteoarthritic cartilage. Icing is a good consideration for osteoarthritic pets with flares. It may also help after a period of exercise or before bedtime. Ice cubes or frozen vegetables are not recommended because they have large air pockets that decrease cold conduction. Ice bags (filled with ice chips or crushed ice) or cold packs provide more effective cold delivery. Most cold packs reach therapeutic temperatures after 2 hours in a freezer. For long-haired patients, place and hold an ice bag or cold pack directly on the pet's arthritic joint or joints and secure it with a self-adhesive band. A pillowcase may be used between the cold pack or bag and the skin in patients with short or no hair. Some cold packs have a built-in self-adhesive band. A neoprene

sleeve may also be used to secure a cold pack or bag. Icing may last for 10 to 15 minutes. Most patients tolerate the treatment. The person applying the ice should make sure the patient is not uncomfortable and that the skin surface feels cold to the touch after icing is complete.

The short- and long-term effects of massage on companion animals are not known. Massage may decrease myofascial pain and muscle tension. Nonpharmacologic options for central pain management include low-level heating; massage; and possibly acupuncture, acupressure, and electroacupuncture. These methods primarily stimulate A β sensory fibers with conduction velocities that are more rapid (30 to 70 m/sec) than A δ (12 to 30 m/sec) and C fibers (0.5 to 3 m/sec).

Heat is widely considered to impact OA patients in pain positively. The use of heat is twofold. Low-level heat (elevation of tissue temperature by 1°C to 2°C) relieves pain through the stimulation of nonnociceptive A β sensory fibers, as well as the vasodilation and normalization of blood flow. This low-level tissue relaxation may be achieved by keeping osteoarthritic patients in relatively dry and warm temperatures throughout the day (e.g., sleeping in heated indoor environments or providing heated beds). More intense heat (elevation of tissue temperature by 3°C to 4°C) is used to increase the effectiveness of stretching while minimizing tissue damage. Intense heating is most often applied by a health care professional using a hot pack that is heated by a Hydrocollator or microwave oven. Four layers of dry towels are generally placed between a hot pack and the skin, and heat is generally applied for 15 to 20 minutes. Caution must be used when placing a hot pack on a dog because burns can occur. Initially the packs may not appear excessively hot to the touch, but they can induce thermal damage after several minutes of contact. Therefore it's important to check for excessive redness, skin swelling, or blistering every few minutes during intense-heat therapy.

Maintaining Fitness and Limb Strength

Adult arthritic patients often present with excessive body weight. Although weight loss in dogs is an area that has received much increased attention in recent years, little scientific information regarding the effectiveness of various weight loss plans on overweight and arthritic dogs has been published. Weight loss of 11% to 18% body weight had a clearly beneficial effect on lameness score at a walk and trot in a report involving nine overweight arthritic dogs (Impellizeri et al., 2000). The lifelong benefits of having a lighter body weight on OA, NSAID use, and longevity have been clearly documented in the Labrador retriever lifelong study mentioned previously (Smith et al., 2006). In that study, compared to their overweight counterparts, the lighter dogs required half the NSAIDs over their lifetime and lived 1.8 years longer. However, for both groups lack of mobility late in life because of OA was the dominant cause of euthanasia (Lawler et al., 2005). This study proved that OA progressed more slowly and was more easily controlled in lighter dogs. Similarly, OA was a major reason for euthanasia of military working dogs. Weekly weight loss rates of 1% to 2% body weight are recommended for overweight dogs. This may

be achieved by feeding an amount approximately equivalent to 60% of the calories needed to maintain current body weight.

Muscle strength has been shown to decrease in humans with OA potentially as a result of limb disuse and the reflex inhibition of the contraction of muscles adjacent to arthritic joints. This loss of strength is both quantitative (caused by a loss of muscle mass) and qualitative (caused by a loss of muscle performance). Loss of strength has not been assessed in arthritic dogs to our knowledge. However, loss of muscle mass is universally reported in dogs with chronic hip dysplasia. Maintaining muscle strength is achieved through active exercises with few exceptions. These exceptions include neuromuscular electrical stimulation and active range-of-motion therapy. Neuromuscular electrical stimulation may be considered in arthritic dogs with severe loss of muscle strength who cannot exercise successfully because of severe pain or limb disuse. However, as a general rule it is simpler and more effective to use adapted therapeutic exercises for arthritic patients (Table 244-1).

Cardiovascular fitness and muscle endurance have been poorly described in dogs. Based on the anticipated impact of OA in dogs, it appears reasonable to maintain a good cardiovascular fitness and muscle endurance through regular aerobic physical activities. The building of muscle endurance requires repeated motion over several minutes. Such endurance building is unlikely to be achieved through self-driven activities in areas with limited space such as leaving a dog unattended in an average fenced-in backyard.

As mentioned previously, little is known about the impact of hip arthritis on joint motion; dysplastic hip joints seemingly lose extension but not flexion. A loss of hip extension of 30 degrees or more likely will lead to the dog's inability to gallop, trot, jump up, or climb steps or stairs. Therefore it appears beneficial to assess joint motion in dogs with chronic hip dysplasia. Since it is much easier to maintain joint motion than to regain it when lost, it seems reasonable to recommend intermittent physical activity

Table 244-1

Therapeutic Exercises Potentially Included in the Management of Canine Hip Dysplasia

Purpose	Possible Therapeutic Exercises
Increasing limb strength	Daily walk or trot longer than 10 minutes; tunnel-walk repetitions; sit-to-stand and stand-to-sit repetitions
Increasing core strength	Daily walk or trot longer than 10 minutes; swimming
Increasing cardiovascular fitness	Daily walk or trot longer than 10 minutes
Stretching pelvic limbs	Climbing up slopes, hills, and stairs; low jumps
Increasing proprioception	Daily walk or trot longer than 10 minutes; walk on soft surfaces: sand, mulch, gravel, leaves, grass; teeter-totter or pole weaving

that leads to enhanced hip joint extension (compared to a walk on a flat surface) without creating significant clinical signs. These activities may include walking uphill or dancing backward (Weigel et al., 2005). If regaining joint motion is deemed important, a stretching program may be implemented. Stretching is more effective when tissues are heated immediately before and during the stretching session. We empirically recommend performing 10 to 15 repetitions of 20- to 40-second-long sustained stretches during each session. Sessions may be performed two to three times per day. With chronic loss of motion, a gain of 3 to 5 degrees of joint motion per week is anticipated.

Although little is known about the negative impact of naturally occurring OA on proprioception in dogs, there is clear evidence that osteoarthritis progresses rapidly in patients with joint injuries that have sensory deficits. In older humans with decreased proprioception, balance exercises readily improve proprioception. In dogs with OA it is logical to dedicate a small portion of exercise programs to exercises requiring rapid and unpredictable side-to-side weight shifts and to a lesser extent front-to-back and back-to-front weight shifts. These exercises may include walking on soft or irregular surfaces and gentle agility exercises, including pole weaving and walking on a teeter-totter, dog walk, or over low rails.

Choosing a Treatment Program

Dysplastic dogs with minor locomotion problems will have a treatment program focused on decreasing pain, maintaining limb and core strength, stretching affected joints, and stimulating proprioception. Pain management is generally achieved with simple pharmacologic steps, rest, and exercise supervision and customization. Pharmacologic and other forms of pain relief may be intermittent as long as dogs adhere to a long-term exercise program.

Because OA screening is not done routinely in dogs, OA is most often discovered in its later stages. Losing mobility because of severe OA is common in large-breed dogs. For patients with severe OA, it is critically important to implement all possible support strategies to decrease the impact of the disease on the dog's well-being and mobility. These may include multimodal pharmacologic management, ice, heat, massage, acupuncture, acupressure, electroacupuncture, transcutaneous electrical nerve stimulation, and rest. Once pain is managed, it is important to initiate an initially conservative and subsequently progressive exercise program. Patients with severe OA may need temporary or permanent ambulation assistance. Slings are the most common and cost-effective

ambulation assistance devices. Severely impaired dogs may benefit from an ambulation cart. Overall a management program for companion animals with OA should be simple and logical. Managing pain is the first priority for all patients. The program must then address the most critical aspects of each patient's unique situation and over time improve the patient's mobility, strength, proprioception and, above all, quality of life.

Treatment of Animals With Spinal and Musculoskeletal Pain

JOAN R. COATES, *Columbia, Missouri*

Pain is a complex yet continually evolving issue in both human and veterinary medicine. In animals, pain has been defined as “an aversive sensory and emotional experience (a perception), which elicits protective motor actions, results in learned avoidance, and may modify species-specific traits of behavior, including social behavior.” (Kitchell, 1987). According to the American Veterinary Medical Association guidelines in recent years, pain management has become an important part of any standard of care when treating our veterinary patients (Colloquium, 1987). Understanding underlying mechanisms of specific pain types (Table 245-1) will assist with the diagnostic approach and establishment of appropriate pharmacologic and clinical interventions for pain management.

CLINICAL ASPECTS OF PAIN INFLUENCING TREATMENT

Pathologic states of clinical pain can be classified as inflammatory pain or neuropathic pain (Muir and Woolf, 2001). Tissue damage or inflammation produces pain through stimulation of nociceptors that are sensitive to mechanical, thermal, and chemical stimuli. Neuropathic pain occurs with injury to neural tissue and represents abnormalities in transmission and somatosensory processing in the peripheral or central nervous system. Some disease processes encompass both nociceptive/inflammatory and neuropathic pain mechanisms. Cancers can infiltrate and compress neural tissue and pain-sensitive structures or cause unlocalizable pain through paraneoplastic effects (Ogilvie and Moore, 2006). Pain associated with chemotherapy and radiation may result from induced axonal injury and vascular compromise.

Pain can be characterized by a careful history to obtain mode of onset and temporal evolution (Table 245-2). Pain in humans is classified based on duration as acute or chronic (Kitchell, 1987). Acute monophasic pain often has an obvious underlying pathologic process that requires immediate clinical intervention to provide relief. Pain is classified as chronic if it exists for more than 6 months. Chronic pain associated with nonprogressive or slowly progressive disease is characteristic of musculoskeletal and neuropathic pain syndromes. The underlying disease process may be apparent, but the associated pain often requires pharmacologic and physical therapies. Pain also is characterized based on site of origin (Kitchell, 1987). It is important to identify factors that exacerbate or relieve

the pain. Previous therapy also may influence the disease course.

In human medicine the patient has the ability to record the intensity of pain. Pain intensity in animals is measured using physiologic data and behavioral observation (Conzemius and Hill, 1999; Lorenz and Kornegay, 2004). Examples of physiologic data include heart and respiratory rates; blood pressure; and serum concentrations of cortisol, glucose, and norepinephrine (Holton et al 1998a). Lack of validated diagnostic techniques and pain-scoring systems in veterinary medicine compound the difficulty to reliably assess behaviors associated with pain. Despite establishment of accuracy, significant variability exists among trained observers when using pain-rating scales in veterinary medicine (Holton et al 1998b). Survey instruments for measuring pain are being developed to allow consistency and objectivity of responses for monitoring pain and effects of therapeutic interventions: www.gla.ac.uk/vet/research/cascience/painandwelfare/cmps.htm.

Differential Diagnosis

Determining the underlying cause for inflammatory and neuropathic pain can help guide appropriate treatment strategies and pain management. The neurologic and orthopedic examinations assist with establishment of differential diagnosis. Disorders of chronic onset and neuropathic pain can be more difficult to manage than those of acute onset and inflammatory pain. Spinal and musculoskeletal pain occur in diseases or disorders associated with compression, inflammation, or trauma of pain-sensitive tissues (Table 245-3) (Lorenz and Kornegay, 2004; Platt, 2004).

TREATMENT OF CLINICAL PAIN

Pain management includes determining the cause to the fullest extent and instituting a treatment plan that has established safety and efficacy. An effective treatment plan provides acceptable analgesia with few side effects. In veterinary medicine this may include clinical interventions and pharmacologic and rehabilitative approaches singly or in combination. Currently multicenter, randomized, controlled studies are lacking for management of clinical pain in veterinary medicine. Thus guidelines for pain management often are empirically based. Goals are to reduce pain and improve function as much as possible. Efficacy, tolerability, cost, and safety need consideration with any type of pharmacologic therapy. Routes

of administration may factor into effective pain control. Different routes of administration include oral, parenteral (intravenous, intramuscular, subcutaneous), epidural, transdermal, transmucosal, and local nerve blocks (Ogilvie and Moore, 2006). Considerations should also be given for short- and long-term therapeutic regimens (also see Chapter 2).

Table 245-1

Nomenclature Used for Description of Pain

Term	Definition
Dysesthesia*	Any abnormal sensation described as unpleasant by patient
Hyperalgesia	Exaggerated pain response from a normally painful stimulus
Hyperpathia	Abnormally painful and exaggerated reaction to a painful stimulus
Hyperesthesia (hypesthesia)	Exaggerated perception of touch stimulus
Allodynia*	Abnormal perception of pain from a normally nonpainful mechanical or thermal stimulus (delay in perception)
Hypoalgesia (hypalgesia)	Decreased sensitivity and raised threshold to painful stimuli
Anesthesia	Reduced perception of all sensation
Analgesia	Reduced perception of pain stimulus
Paresthesia*	Spontaneous abnormal sensation that is not unpleasant
Causalgia*	Burning pain in distribution of one or more peripheral nerves

*Symptoms used to describe pain in humans but difficult to recognize as clinical signs in animals.

Identification of mechanisms underlying signal transduction and transmission and processing of painful stimuli has led to the development of drugs that target chemical mediators of pain (Muir and Woolf, 2001). Steroidal and nonsteroidal antiinflammatory drugs (NSAIDs) are effective for inflammation; opioids and α -2 agonists modulate excitatory and inhibitory neuronal

Table 245-2

Clinical Characteristics of Pain

Characteristics	Descriptors
Location	<i>Nociceptive</i> (musculoskeletal—axial and appendicular; muscles), <i>neuropathic</i>
Distribution	Focal, multifocal, diffuse, referred
Mode of onset	Acute (hours to days), chronic (weeks to >3 months)
Temporal evolution	Static, progressive, intermittent, recurrent
Severity	Mild, moderate, severe
Associated behaviors	Vocalization; rubbing, chewing, biting affected area; stiff and stilted gait; guarding; reluctance to move, jump, or climb stairs; unwilling to drink or eat from bowl; attitude change (depression, aggression); unable to obtain resting position or restlessness; anorexia; autonomic signs
Relieving factors	Specific postures and exercise may relieve joint pain, limit movements/activity, therapeutics
Provoking factors	Palpation, specific movements/activities, exercise

Table 245-3

Differentials for Clinical Pain Associated With the Musculoskeletal System

Differential Category	Nociceptive/Inflammatory Pain	Neuropathic Pain
Degenerative	Degenerative joint disease (axial and appendicular skeleton)	IVDD (types I and II), caudal cervical spondylomyelopathy, degenerative lumbosacral syndrome, paraspinal cysts
Anomalous	Axial/appendicular skeletal malformation	Spinal malformation, caudal occipital malformation syndrome (Chiari-like malformation), syringohydromyelia, atlantoaxial instability
Metabolic	Hyperparathyroidism	Hyperparathyroidism
Neoplastic	Primary and metastatic neoplasms of bone, joint, muscle, spine, meninges	Malignant nerve sheath tumor, brain tumor, extradural, intradural/extramedullary, intramedullary (less likely) spinal cord tumors, vertebral/skull tumors, metastatic tumors, paraneoplastic
Nutritional	Hypervitaminosis A	
Inflammatory (infectious/noninfectious)	Osteoarthritis, osteomyelitis, hypertrophic osteodystrophy, infectious and noninfectious meningitis, diskospondylitis, spinal empyema	Meningitis, spinal empyema
Immune	Osteoarthritis, myositis, systemic lupus erythema, rheumatoid disease	Chronic osteoarthritis
Idiopathic		Spinal arachnoid diverticulum
Traumatic	Fracture, type I IVDD	Spinal fracture, type I IVDD extrusion, neuroma, nerve avulsion, syrinx
Vascular	Osteonecrosis	Ischemic neuromyopathy, extradural hemorrhage

IVDD, Intervertebral disk disease.

activity; and local anesthetics suppress electrical impulses (Table 245-4). Nonopioid drugs act at the nociceptor level and alter transduction processes of pain. Opioids alter transmission and perception of pain in the central nervous system. Various pharmacologic regimens most often are based on complementary mechanisms of action that need to be combined in a rational fashion (Muir and Woolf, 2001). For chronic pain combination therapy or multimodality therapies may be more effective than a single agent. NSAIDs appear to have synergistic effects with

opioids and may allow for lower dosage of both (Muir and Woolf, 2001; Mathews, 2002).

Nonopioid Analgesics

Glucocorticoids

Inflammatory pain can be alleviated through antiinflammatory actions of glucocorticoids by inducing lymphopenia, reducing differentiation and proliferation of lymphocytes, disrupting cytokine function and intercellular

Table 245-4

Common Drugs Used for Pain Management in Dogs And Cats

Generic Name	Proprietary Name (Company)	Dosage for Dogs	Dosage for Cats
Glucocorticoids			
Prednisone, prednisolone	Generic	0.5-1 mg/kg q12-24h PO	0.5-1 mg/kg or higher q12-24h, PO (prednisolone)
Dexamethasone	Generic	0.07-0.15 mg/kg q12-24h, IV, IM, PO	0.07-0.15 mg/kg q12-24h IV, IM, PO
Nonsteroidal Antiinflammatory Drugs			
Aspirin	Generic	10-25 mg/kg q12h PO	10 mg/kg q48h PO
Etodolac	Etogesic (Fort Dodge Animal Health)	10-15 mg/kg q24h PO	Not used
Carprofen	Rimadyl (Pfizer Animal Health)	2-2.2 mg/kg q12h PO	2-2.2 mg/kg q12h PO (extra-label use)
Ketoprofen	Orudis KT (White-Hall Robins)	1-2 mg/kg q24h PO (extra label use)	1-2 mg/kg q24h PO (extra label use)
Meloxicam	Metacam (Boehringer Ingelheim Vetmedica)	0.1-0.2 mg/kg q24h PO	0.1-0.2 mg/kg q24h for 1-2 days; then 0.025 mg/kg 2-3 times/week PO (extra-label use)
Deracoxib	Deramaxx (Novartis Animal Health)	1-2 mg/kg q24h PO	Not used
Tepoxalin	Zubrin (Schering-Plough Animal Health)	10 mg/kg q24h PO	Not used
Firocoxib	Previcox (Merial)	5 mg/kg q24h PO	Not used
Opioids			
Fentanyl Citrate	Sublimaze (Taylor), Duragesic (Janssen), generic	5 mcg/kg/h CRI 5-10 mcg/kg q2h IV, IM, SQ; 50 mcg/10-20 kg q3-5 days, transdermal	2 mcg/kg/h IV CRI 5-10 mcg/kg q2h IV, IM, SQ; 50 mcg q3-5 days, transdermal
Hydromorphone	Dilaudid (Abbott); generic	0.1-0.2 mg/kg q4-6h IV, IM	0.1-0.2 mg/kg q4-6h IV, IM
Morphine	Generic	0.1-1 mg/kg q4h IV, IM, SQ; q8h PO	0.05-0.1 mg/kg q3-6h IM, SQ
Oxymorphone	Numorphan (Endo Labs)	0.1-0.2 mg/kg initial; redose with ½ dose q1-2h IV, IM, SQ	0.1-0.2 mg/kg initial; redose with ½ dose q1-2h IV, IM, SQ
Buprenorphine	Buprenex (Reckitt Benckiser)	0.005-0.02 mg/kg q4-8h IV, IM, SQ	0.005-0.02 mg/kg q4-8h IV, IM
Butorphanol	Torbugesic (Fort Dodge)	1-4 mg/kg q2-4h, IV, IM, SQ; q6h PO	1.5 mg/kg q2-6h IV, SQ; q4-8h PO
α-2 Agonists			
Medetomidine	Domitor (Pfizer)	5-10 mcg/kg IM or SQ; 1-4 mcg/kg IV	5-10 mcg/kg IM or SQ; 1-4 mcg/kg IV
Xylazine	Rompun (Miles); Generic	0.1-0.5 mg/kg q12h IV, IM, SQ	0.1-0.5 mg/kg q12h IV, IM, SQ
Local (Epidural) Anesthetics			
Bupivacaine	Marcaine (Abbott)	1 ml/10 cm	1 ml/10 cm
Lidocaine	Generic	4.4 mg/kg	4.4 mg/kg
Mepivacaine	Carbocaine (Abbott)	0.5 ml q30sec until absent reflex; not exceeding 8 mg/kg	0.5 ml q30sec until absent reflex; not exceeding 8 mg/kg
Other Drugs			
Tramadol	Ultram (Ortho-McNeil); generic	2-4 mg/kg q6-12h PO	2 mg/kg q12h PO
Amitriptyline	Elavil (Zeneca)	1-4 mg/kg q24h PO	2-4 mg/cat/day PO
Gabapentin	Neurontin (Pfizer); Generic	3-10 mg/kg q8-24h PO	3-10 mg/kg PO q8-24h PO

CRI, Continuous rate infusion; IM, intramuscular; IV, intravenous.

trafficking among leukocytes, and inhibiting macrophage functions. These mechanisms of action suppress aspects of the inflammatory response by reduction of cell numbers, phagocytosis, migration, and antigen presenting and processing. Glucocorticoids also inhibit phospholipase activity, which converts membrane-released phospholipids to arachidonic acid.

Specific disease processes vary widely in optimal corticosteroid usage (Platt, Abramson, and Garosi, 2005). It is important to obtain a confirmatory diagnosis before glucocorticoid usage. Initial rapid improvements without a differential diagnosis can be misleading. Unsupervised chronic use of corticosteroids without monitoring can lead to deleterious side effects (Behrend and Kemppainen, 1997). Protocols with high-dose regimens should not be combined with antiinflammatory regimens. For compressive spinal cord disease, dexamethasone and prednisone have been administered at antiinflammatory doses to control inflammatory response and pain and to reduce spinal cord edema. Concurrently strict cage rest is important to prevent excessive activity in animals with spinal disease. Only a short-term antiinflammatory regimen of prednisone is recommended. Immunosuppressive regimens are used for immune-mediated causes of musculoskeletal disease. Gradual taper is instituted according to the patient's overall condition.

Nonsteroidal Antiinflammatory Drugs

NSAIDs are most often used for treatment of pain associated with inflammatory conditions but may also be useful in noninflammatory conditions and chronic pain. The antiinflammatory properties of NSAIDs are caused primarily by inhibition of cyclooxygenase (COX) isoenzymes 1 and 2 that synthesize prostanoids from arachidonic acid (Fig. 245-1). COX-1 is constitutive; whereas COX-2 is induced by growth factors, cytokines, and tumor promoters. COX-2 ultimately is synthesized by

macrophages and inflammatory cells in the presence of tissue injury and inflammation. Secondary increases in prostanoids amplify nociceptive input and transmission in the peripheral and central nervous systems. COX-2 is involved to a greater degree than COX-1 in pain transmission after tissue injury (Curry, Cogar, and Cook, 2005; Mathews, 2002). Arachidonic acid also is metabolized by lipoxygenase to leukotrienes, which participate as inflammatory mediators (see Fig. 245-1).

Common subclasses of NSAIDs used in dogs and cats include salicylates (aspirin), propionates, indoles, and fenamates. Some NSAIDs have both COX-1 and COX-2 inhibitory effects (aspirin, ketoprofen, etolac), whereas others selectively inhibit COX-2 or are COX-1 sparing (carprofen, meloxicam, deracoxib, tepoxalin, firocoxib) (Curry, Cogar, and Cook, 2005) (see Fig. 245-1). Since COX-2 appears to play a significant role in nociceptive transmission, drugs that spare COX-1 should be sufficient, with fewer adverse effects in pain management. Inhibition of COX isoenzymes may cause arachidonic acid metabolites to enter the lipoxygenase pathway and increase the inflammatory effects of leukotrienes. Some NSAIDs have been shown to inhibit both COX and lipoxygenase (ketoprofen and tepoxalin). Most NSAIDs undergo hepatic metabolism and are eliminated through the enterohepatic circulation or by renal clearance. Adverse reactions associated with NSAIDs occur in the gastrointestinal tract, liver, and kidney. Other side effects may include coagulopathy, inhibition of healing, and altered bone formation. The plethora of different NSAIDs (see Table 245-4) available for use in dogs and cats provides the practitioner with a choice for the most appropriate NSAID that best complements pain management while minimizing patient side effects (Curry, Cogar, and Cook, 2005). Response to a specific NSAID may vary with each individual patient and the type of pain (Mathews, 2002). If one NSAID does not appear to remedy the pain, an alternative NSAID or adjunctive use of a different class of

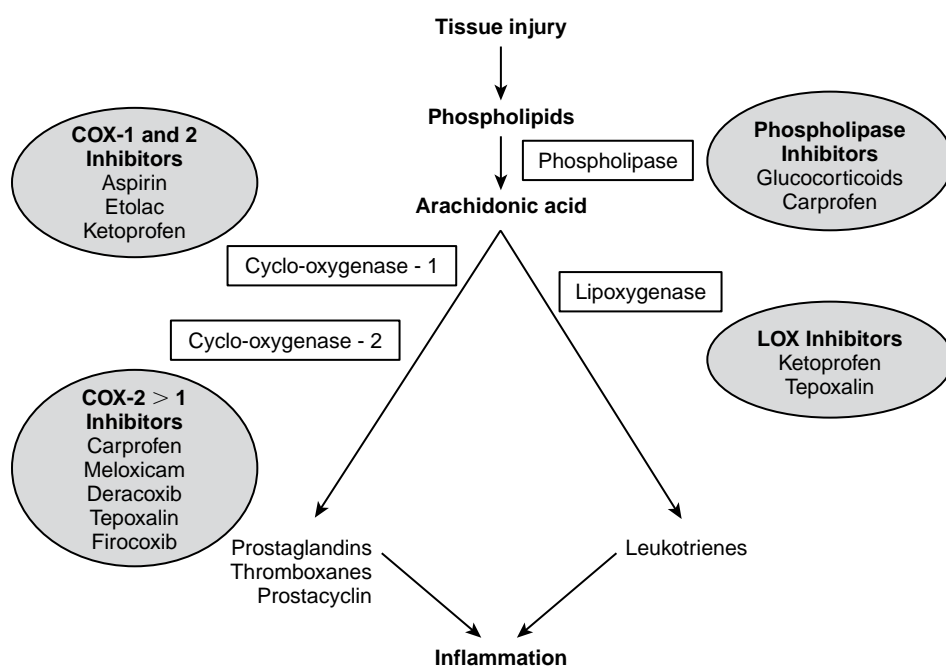

Fig. 245-1 Schematic depicting pharmacologic inhibitors of arachidonic acid metabolism and the cyclooxygenase (COX) and lipoxygenase (LOX) pathways.

analgesic needs consideration. Concurrent use of other NSAIDs or glucocorticoids should be avoided. A “wash-out” period (48 to 72 hours) should be allowed before administering a different NSAID.

Opioid Analgesics

Opioid analgesics are classified into various groups based on their pharmacologic activity, potency, and clinical use. Type and dosage of opioid selection varies, depending on severity of pain (see Table 245-4). Opioid analgesics modify pain perception and behavioral reactions and relieve anxiety and distress. Pharmacologic dosages of opiates supplement the natural activity of endogenous opiates and suppress neurons in the spine and medulla that transmit pain (Jenkins, 1987). Effectiveness of pharmacologic opiates may vary with route of administration: parenteral, epidural, rectal, oral, and transdermal (fentanyl patch). Direct delivery of opioids to the spinal cord (epidural anesthesia) is used to produce effective anesthesia for surgical procedures. Opioids are more effective for postsurgical and traumatic pain (Chapter 2) and considered less effective for neuropathic pain (Lorenz and Kornegay, 2004; Muir and Woolf, 2001). Opioids that are pure agonists may provide more effective pain control than agonist-antagonist opioids. Tolerance to opiate effects may develop during repeated and chronic administration. Side effects may include altered consciousness, including dysphoria and respiratory depression.

Other Pharmacologic Therapies

α -2 Agonists such as xylazine and medetomidine are centrally acting and possess sedative, muscle relaxant, and analgesic properties (see Table 245-4). Analgesic effects are enhanced when used in combination with opioids. In humans the mainstay for chronic treatment of neuropathic pain is tricyclic antidepressants and anticonvulsants (Truini and Cruccu, 2006). Analgesic actions of antidepressant drugs are most likely related to effects on endogenous pain-modulating pathways (Muir and Woolf, 2001). The anticonvulsant gabapentin has been extensively investigated and proven to be effective for a variety of neuropathic pains. The mechanism of action is unclear. Gabapentin is an analog of γ -aminobutyric acid, the major inhibitory neurotransmitter in the central nervous system. Gabapentin may alter voltage-sensitive ion channels. Unlike many analgesics, gabapentin is minimally metabolized by the liver and eliminated by renal clearance. In veterinary patients gabapentin has been used empirically for management of refractory neuropathic pain. Muscle relaxants (e.g., diazepam, methocarbamol) can be administered for musculoskeletal pains that cause muscle spasm.

Physical Therapy

Physical therapy during recovery from orthopedic and neurologic disorders is important not only for strengthening and increasing flexibility but also for pain reduction (Sherman and Olby, 2004). Physical therapy in recumbent patients begins with passive range of motion (ROM).

Joints of limbs are extended and flexed through normal ROM 5 to 10 minutes several times a day. Active ROM includes swimming and standing exercises. Water buoyancy aids in rehabilitation of weak muscles and painful joints by minimizing the amount of weight-bearing on the joint while generating the gait cycle. As the patient begins to ambulate without assistance, therapeutic exercising includes standing and more dynamic ambulation activities, which serve to enhance ROM, muscle strength, balance, and overall daily function. Static and mechanical forms of stretching techniques are performed in conjunction with ROM exercises to prevent fibrosis and contracture of joints and muscles. Other modalities of physical therapy and supplemental therapies that complement mobility therapies include thermal, electrical stimulation, massage, ultrasonographic, acupuncture, and weight loss. Rehabilitation protocols are individually tailored to meet patient's needs during the recovery process.

Surgical Intervention in Spinal Pain

Patients with compressive myelopathy or radiculopathy often require decompressive and/or stabilization procedures (See Chapters 237 and 238). Outcomes in dogs with a rapid onset and defined compressive cause of myelopathy often are favorable (Olby et al., 2003). Long-term outcome of surgery in dogs with chronic-onset compressive or destabilizing myelopathy remains unknown. In humans electrical stimulation or neuroablative surgical procedures have been used to treat central pain with limited success.

CHAPTER 246

Physical Therapy and Rehabilitation of Neurologic Patients

DARRYL L. MILLIS, *Knoxville, Tennessee*

Physical rehabilitation is an important part of therapy for patients with neurologic conditions. Rehabilitation may be used in a variety of situations, including medical and postsurgical neurologic conditions, peripheral nerve conditions, and neuromuscular disorders. Both upper and lower motor neuron conditions may benefit from rehabilitation. It is important to realize that physical rehabilitation should be used in conjunction with other standard treatments such as decompressive surgery of an intervertebral disk herniation rather than as the primary treatment. The specific rehabilitation plan should be based on the type and severity of the neurologic condition and the specific needs of the patient. In general, maintaining joint function and range of motion, improving balance and proprioception, preserving or increasing muscle strength, and improving overall function are goals for the neurologic patient. Rehabilitation may increase the rate of recovery in patients that are expected to recover eventually from their neurologic condition. In patients with progressive neurologic conditions such as degenerative myelopathy, rehabilitation may retard deterioration of the patient.

JOINT FUNCTION AND PASSIVE RANGE OF MOTION

Placing each joint through a normal range of motion helps to maintain joint health in patients with neurologic deficits. Reduced or unopposed muscle tone of either the flexor or extensor muscles may result in contracture of

the joints of the limb if a complete range of motion is not achieved at least daily. Passive range of motion (PROM) should be performed with the patient lying in lateral recumbency on a well-padded area, and the uppermost limbs put through gentle flexion and extension of each joint within the patient's comfortable range of motion. Each joint should be moved through 15 to 20 cycles. As the animal progresses, the entire limb may be put through an exaggerated gait movement, called *range of motion through functional patterns or bicycling*. These movements should be performed for 15 to 20 repetitions. The patient is then repositioned with the other side down, and the exercises are repeated on the other limbs. These exercises should be performed two to four times per day until the patient is able to ambulate or has reached a recovery plateau.

PROM may be combined with stretching in joints that have already lost some range of motion. The affected joint and adjacent muscles should be prewarmed with a warm pack, massage, or both. PROM should be applied to the joint, and on reaching the respective end point of flexion and extension the therapist should exert a gentle stretch for 15 seconds to maintain the joint at the upper limits of flexion or extension, being careful not to induce unnecessary discomfort.

In patients with limited voluntary movement, eliciting a flexor reflex of the forelimb or hind limb results in some muscle contraction, joint motion, and sensory input to the limb and spinal cord. As the limb retracts, additional strengthening may be achieved by providing resistance to limb motion. In patients with poor-to-absent pain

perception, caution must be used in eliciting the flexor reflex to avoid damage to the skin and other soft tissues of the toes.

INITIAL STRENGTH, BALANCE, AND PROPRIOCEPTION EXERCISES FOR THE NEUROLOGIC PATIENT

A variety of exercises help to improve strength, balance, and coordination. These exercises are especially useful in patients that have voluntary movement with varying degrees of proprioceptive deficits.

Standing Exercises

The most basic coordination exercise is the standing exercise. It entails having the patient in a standing position with all four limbs placed in a square, symmetric position on the ground with support of the body provided by a sling or other assistive device. As the patient begins to weaken and collapse to the ground, the therapist lifts the dog back into a square standing position. Initially standing exercises are performed for 1 to 3 minutes, with the goal of standing unassisted for 5 minutes. At this point the patient likely has adequate strength and stamina to begin other exercises. Standing in water is also an excellent exercise because the buoyancy of the water helps to support the body while the dog actively tries to stand and move the limbs. Exercise in water must always be attended to prevent drowning! When an animal is able to stand (independently or with some assistance), activities to improve balance may begin. These exercises should be conducted on a nonslip surface to reduce the risk of falling.

Weight Shifting

While the animal is standing, a treat or ball may be used to encourage weight shifting. The therapist should move the treat or ball, allowing the dog to move its head and follow the treat up and down and side to side. He or she should start with small movements and progress to larger, more challenging movements. The movement of the head causes the dog's center of gravity to shift, and the dog must shift its weight to maintain its balance.

The handler may also disturb the animal's balance by gently pushing it at the hips or shoulder. The goal is to disturb its balance just enough so the animal can recover, being careful not to push too hard. Some dogs become conditioned to this activity and shift their weight toward the therapist to prevent being pushed toward the affected side. In this case a rebound weight shift may be effective, with the therapist gently pushing the animal toward the affected side. When the animal shifts its weight to resist, the therapist suddenly releases pressure and simultaneously pushes gently toward the unaffected side. This results in a sudden unbalancing; the animal initially shifts its weight toward the unaffected side, but to keep from falling it shifts its weight back to the affected side. Additional challenges may be added by slowly moving a supporting towel back and forth to force the dog to shift its weight. A limb may also be lifted off the ground. This

requires the patient to adjust and redistribute its weight to the remaining three limbs. This exercise may be performed on each limb on an alternating basis. Weight shifts may also be performed during walking. As the animal is walked, the handler gently bumps or pushes the animal to one side. Caution should be exercised to avoid falls and injury.

Assisted Ambulation/Gait Training

If a dog is unable to walk independently, a sling, towel, harness, or canine cart may be used to support the animal as needed. Encourage the dog to move slowly, allowing time for it to advance the limbs as independently as possible. It may be necessary to manually assist the dog in the sequencing and placement of the limbs. The emphasis is on weight bearing with each and every step, encouraging a slow gait so that neuromuscular coordination and muscle strengthening may occur. Walking in water is beneficial because the animal's weight is partially supported and the limbs typically move at a slower speed than land-based walking. Supported swimming can also provide benefits in patients with severe neurologic conditions; in some cases animals generate some limb movement, even if in an uncoordinated fashion, allowing strengthening and neuromuscular reeducation.

ADVANCED STRENGTH, BALANCE, AND PROPRIOCEPTION EXERCISES FOR THE NEUROLOGIC PATIENT

A platform may be used to rock the dog forward and backward and side to side. A human Biomechanical Ankle Platform System board may be used to help the animal practice proprioceptive positioning on just the forelimbs or the hind limbs. If the goal is to have the animal exercise using all four limbs, a specially made platform must be used that accommodates quadrupeds. It is important to provide support to allow the animal to shift its weight and exercise its proprioceptive mechanism.

Several commercial or homemade objects may also be used for this purpose. Balance balls or rolls are large-diameter exercise round or elongated balls that the patient can be placed on and supported to improve balance, coordination, and strength. The forelimbs are placed on the ball and supported by the handler, requiring the dog to maintain static balance of the caudal trunk and rear limbs. Dynamic balance may also be challenged as the ball or roll is slowly moved forward, backward, and side to side, challenging the rear legs to maintain balance while movement occurs. To address the cranial trunk and forelimbs, the rear limbs are placed over the ball as the forelimbs are asked to balance the body weight during both stance and gentle movements. A balance board is a rectangular piece of plywood with a narrow rod running longitudinally or transversely along the bottom. The board tips in a lateral or cranial-caudal direction, respectively, when the patient stands on it. Cavaletti rails are horizontal poles that are elevated such that the patient must pick its limbs up to step over the poles. Having the patient walk across or stand on a foam mattress or trampoline may also be used to improve balance and coordination.

Balancing and coordination activities may be incorporated into regular walking activities. Altering the texture of the ground challenges the animal's functional walking proprioceptive ability. Standing or walking on foam-rubber mattresses, air mattresses, and trampolines allows the animal to negotiate various surfaces. The patient may also spend part of its walk negotiating cavaletti rails, which challenges the patient's ability to negotiate obstacles of different heights. These exercises should be continued until the patient has a normal or very near-normal gait.

In addition to walking over regular surfaces and surfaces of differing textures, dogs may be walked on the ground or on an underwater treadmill. Walking on a treadmill provides additional challenges to proprioception and is valuable in rehabilitation of human stroke patients. Walking on an underwater treadmill allows support of the patient's body weight, and the water provides resistance of movement and muscle strengthening. Other strengthening activities include sit-to-stand exercises, walking with weights strapped on the limbs, or placing elastic bands around the distal limb with the therapist providing gentle resistance during motion.

ASSISTIVE DEVICES

Assistive devices provide increased independence for the pet, give support to a weak or nonfunctioning body part, and help the handler maintain proper body mechanics while performing therapy. These devices can also help to protect the feet during walking to prevent ulcers from forming. They are available in a variety of forms, including slings, two-wheeled and four-wheeled carts, boots, and prosthetics.

Boots are an excellent way to protect the feet when an animal with neurologic deficits is knuckling or turning its feet over and walking on the dorsum of the foot. Animals with poor proprioception are unaware of the placement of their distal limbs and tend to walk on the dorsum of their paws or drag the nails when walking. Boots act as socklike coverings that are securely fastened by Velcro straps at the top. Most have a rubber sole to prevent slipping and are machine washable. It is important to remove the boots periodically (several times daily) to assess skin condition, especially in neurologically impaired patients, and, if possible, to increase weight bearing and proprioception through the bottom of the pads when performing therapeutic exercise. If not fitted properly, boots can interrupt circulation, become cumbersome and impede gait patterns or strides, and potentially cause more problems if the animal stumbles and falls. Proper fit is essential, and appropriate client education instructions for skin care and rehabilitative exercises must be communicated to the owner.

When choosing the proper boot, the handler should ascertain that it is washable, waterproof or water resistant, and constructed of durable material that will not wear down quickly. The bottom surface should have a nonskid material that prevents slipping. Old socks may also be used to help provide padding; however, caution must be exercised if the top is secured with tape to avoid cutting off circulation.

Slings come in a variety of shapes and sizes. Some products may be strapped around the belly or fitted for the forelimbs, hind limbs, or both. Slings should have long handheld straps attached to allow proper body mechanics to avoid personal injury to the handler when supporting the pet. These devices aid in transitioning a recumbent animal to a standing position and are especially useful for larger dogs. A sling can also assist with ambulation and prevent falls on slippery floors, especially after surgery, thereby avoiding further injury to the animal. Support slings are also available for forelimb assistance.

Slings are available in a variety of sizes to provide the best fit. It is important to select a properly sized sling for safety and comfort of the patient. The sling used for the forelimbs should not obstruct respiration, and urine flow should not be compromised with hind limb slings in male dogs. A sling should have a soft lining against the animal's skin to avoid irritation and sores, and the material should be washable. The sling must not be too thin, especially around the groin and belly region, to avoid excessive pressure and development of sores. Slings are also useful during the later phases of rehabilitation for supporting standing during therapeutic exercises such as repeated sit to stands. When documenting patient progress, the amount of assistance given through sling support can be rated as minimum, moderate, or maximum assistance.

Carts, or canine wheelchairs, provide support, allow independence for the animal, and help prevent the deleterious effects of recumbency. Two- or four-wheeled carts are available for disabled paraplegic or quadriplegic patients. Carts should not be used too early in the course of rehabilitation because dogs may become too dependent on their support. They should be fitted properly according to manufacturers' recommendations. Animals should be supervised at all times when in a cart so that they do not fall down stairs or tip over, and dogs should not be placed in the cart for long periods of time to prevent fatigue. Skin condition should be assessed daily to be certain that no areas of tissue breakdown occur.

MANAGING THE RECUMBENT PATIENT

Some conditions require a lengthy recovery, and animals initially may be recumbent. During this critical time, it is especially important to provide intensive nursing care to avoid serious complications.

Recumbent patients should be placed on a padded bed. An absorbent pad should be placed under the animal if incontinence is an issue. For patients that urinate frequently, it may be necessary to have the animal on an elevated grate that will not allow urine to pool under the patient. Appropriate bladder management must be performed carefully, balancing evacuation of the bladder with minimum trauma while expressing the bladder. Appropriate pharmacologic intervention may be useful to minimize urine retention (see Chapter 207). Animals recumbent for a very long time are at risk for developing decubital ulcers. Dogs with thin skin and prominent bony protuberances such as greyhounds

and whippets are especially prone to developing decubital ulcers. Preventing ulcers is far superior to treating them. Therefore the skin should be assessed each day for redness or other evidence of skin breakdown. Patients should be kept on a soft padded bed and turned every 4 to 6 hours. If redness or irritation of skin is noted, a “donut” may be made to help distribute pressure away from the area.

The environment should be comfortable for the patient. The animal should be moved from a cold, damp environment to a warm, dry inside environment. A soft, well-padded bed or waterbed should be offered. A circulating warm-water blanket may reduce morning stiffness, but an electric heating pad that cycles on and off should be avoided because it may cause burns if the patient cannot get away from it if it is too hot. Consideration should be given to the activities of other pets in the household, because they may be a source of irritation to dogs recovering from neurologic conditions. Changes should be made to minimize climbing stairs. Commercial ramps or steps are available to help patients get into cars or on furniture.

REHABILITATION CONSIDERATIONS IN PATIENTS WITH SPECIFIC CONDITIONS

Intervertebral Disk Disease

Canine patients with intervertebral disk disease are presented with a variety of clinical manifestations. Most have thoracolumbar disk disease, although cervical disk disease is also common. Most dogs have upper motor neuron signs, although lower motor neuron signs may be present in some cases. Finally, consideration must be given to whether a patient has had surgical intervention or if conservative therapy has been initiated. Rehabilitation efforts should be directed to correct decreased or absent superficial or deep pain, decreased or absent motor function, ataxia and proprioceptive deficits, muscle atrophy of variable severity, and tense back and limb muscles.

In most cases it is contraindicated to perform any type of active exercise in animals with acute back pain and neurologic deficits that are managed conservatively because the annulus fibrosis is weak and exercise may worsen the condition. These dogs require strict cage rest until the annulus

Box 246-1

Sample Rehabilitation Program for Dogs With Intervertebral Disk Disease

Step 1: Immediately After Surgery to Supporting Weight

- Cryotherapy of the incision site and underlying tissues to reduce inflammation and swelling of the surgical area for 20-30 minutes TID
- Passive range of motion (PROM) to all joints of the affected limbs, 20 repetitions BID-TID
- Massage of the limb muscles in cases with upper motor neuron lesions; tapotement of the muscles may be beneficial to help maintain muscle tone in cases with lower motor neuron lesions
- Neuromuscular electrical stimulation to the affected muscles is helpful to attenuate muscle atrophy if lower motor neuron signs are present
- Standing exercises instituted the day after surgery to encourage neuromuscular reeducation of the muscles responsible for maintaining normal standing posture and to strengthen muscles to allow weight bearing and ambulation
- Nursing care instituted to recumbent dogs
- Use of assistive devices such as slings for body support and protective boots to help protect feet from injury and to position the foot in a more natural standing position

Step 2: Supporting Weight to Initial Motor Function

- PROM and standing exercises continued
- Standing in water and assisted swimming begun to encourage early motor function
- Weight-shifting exercises in a standing position
- Assisted walking with support

Step 3: Initial Motor Function to Good Motor Function With Proprioceptive Deficits

- Swimming
- Ground treadmill walking with the therapist positioned to assist gait and correct placement of the foot when it is advanced and to help with gait training

- Balancing activities such as a balance board, weight shifts, standing on a physioroll while it is rocked back and forth; varying the speed of ambulation, incorporating “zig-zags” figure eights, circles to the right and left when walking; walking on trampolines or other unstable surfaces

Step 4: Good Motor Function With Proprioceptive Deficits to Near-Normal Gait

- Swimming and treadmill walking continued, with increased speed and length of treadmill walking to help challenge patients to achieve a higher level of functioning
- Stair climbing and sit-to-stand exercises may be added for proprioceptive and strength training
- Balancing activities continued as in step 3
- Walking over raised cavaletti rails
- Jogging may be added as the patient regains proprioceptive functioning

Step 5: Near Normal To Normal Gait

- Activities in previous steps may be continued
- The length of time spent swimming is increased to improve endurance and strength
- Jogging on the treadmill and jogging up and down small stairs may be added to encourage proprioceptive challenges at higher speeds
- Walking over raised cavaletti rails is continued; and, if the patient is able, it may negotiate the rails while jogging
- Playing ball is added as the patient nears return to a normal gait

heals sufficiently to withstand the additional stress of mild activity. Massage, transcutaneous electrical nerve stimulation, and PROM of joints may be administered. After 3 to 6 weeks whirlpool therapy may be used cautiously in patients carefully supported in a sling. Progressive strengthening may be achieved with deep-water aquatic therapy, proprioception exercises on therapy balls or rolls, assisted walking, and dry and underwater treadmill activity.

Postoperative physical rehabilitation is an integral part of the overall care of patients having decompressive surgery and is provided in a stepwise fashion, with activities based on the stage of recovery (Box 246-1).

Degenerative Myelopathy

Although degenerative myelopathy is a progressive condition with no known cure, one study indicated that dogs that received intensive physical rehabilitation had a longer mean survival time (255 days) compared with dogs with moderate (130 days) or no (55 days) therapy (Kathmann et al, 2006). Moreover, affected dogs receiving physical rehabilitation remained ambulatory longer than animals that did not receive physical treatment. A sample rehabilitation program is outlined in Box 246-2.

Box 246-2

Sample Rehabilitation Program for Dogs With Degenerative Myelopathy*

Active Exercises

- Slow leash walking 5-10 minutes at least five times/day
 - If knuckling, place protective boots or use an elastic band around the foot to allow the therapist to correct the position of the paw with each step
- Short, frequent exercise periods are preferred to long exercise periods
- A rolled towel may be taped to the middle of a sling to maintain the hind limbs in a normal position or in slight abduction if the dog has a tendency to adduct the limbs while walking
- Sit-to-stand exercise if the dog is able
- Assistance with a sling if needed or sit-to-stand from an elevated position or in water
- Weight-shifting exercises while standing
- Walking on different surfaces
- Stair climbing, walking uphill

Passive Exercises

- Passive range of motion of each joint of both hind limbs three times/day, 20 repetitions for each joint
- Massage of the paravertebral muscles and limbs, starting distally and working to proximal three times/day
- Hydrotherapy
- If available, walking on underwater treadmill; otherwise, swimming or walking in water, depending on dog's ability at least once a week, 5-20 minutes
 - The type, length, and intensity of the exercise should be adapted to the dog's condition
 - Assistance with a sling is provided as needed
 - Weight shifting while standing in water is encouraged, especially in the later stages

*Modified from Kathmann et al., 2006.

Peripheral Nerve Injury

Currently there are no accurate clinical indicators of whether a peripheral nerve injury will recover and, if so, the degree of recovery that will occur. If a degree of function does return, the functional status of the affected limb will depend on the degree of muscle atrophy that occurs during the period of nerve regeneration and contracture of joints. Muscle atrophy associated with nerve injury is a combination of disuse and degeneration. The ability of the patient to regain functional use of a limb depends on a number of factors, including the severity of nerve injury; the distance through which the nerve must regenerate; the age of the patient; and other associated tendon, soft-tissue and bony damage. Electrical stimulation of denervated muscle during the period of nerve regeneration may help to maintain the integrity of the muscle fibers and their potential functional capacity. Studies have indicated a beneficial effect of electrical stimulation on denervated muscles, with improved morphology and functional capacity of the reinnervated stimulated muscles when compared with nonstimulated controls (Williams, 1996). In addition to electrical stimulation of muscles, it is also important to perform PROM and stretching to help prevent contracture of joints, especially of the digits, as a result of unopposed muscle tone in some peripheral nerve injuries. These exercises must be performed several times daily throughout the recovery period to avoid pathologic shortening of muscle-tendon units and fibrosis of joint capsules. Stimulation of the flexor reflex, standing exercises, aquatic activity, and other weight-bearing exercises may be performed as the patient progresses.

Hypokalemic Myopathy in Cats

BOYD R. JONES, *Dublin, Ireland*

Hypokalemia results from one of the following: reduced potassium intake, increased potassium entry into the cells, or increased potassium loss from the body. Of these causes in cats, renal potassium loss is the most important, especially if such loss is associated with inadequate intake. In healthy cats the daily potassium intake should equal daily loss. Potassium maintains the intracellular fluid volume and normal membrane potential. If the ratio between intracellular and extracellular potassium is altered significantly, the muscle membrane potential of excitatory tissue such as nerve and muscle is affected. Hypokalemia significantly affects muscle membrane activity and muscle function and can, if severe, result in rhabdomyolysis. As potassium is depleted, a progressive increase in the muscle cell resting transmembrane potential (hyperpolarization) results so that the myocyte becomes increasingly refractory to electrical stimulation. Eventually, however, the muscle cell membrane suddenly becomes permeable to sodium ions, and the resulting sudden membrane hypopolarization induces rapid, severe weakness. If the potassium deficit is not corrected, the muscular dysfunction may progress to paralysis. The increase in intracellular sodium (and chloride) often exceeds the degree of potassium depletion that predisposes to rhabdomyolysis by osmotic expansion of the cell (Fettman, 1989). Additional factors that may contribute to the myopathy and rhabdomyolysis are a reduction in muscle blood flow that occurs with exercise and altered muscle carbohydrate metabolism (Fettman, 1989).

There have been numerous reports of polymyopathy in cats associated with a variety of different causes of hypokalemia (Box 247-1). Of these causes, cats with chronic renal failure and Burmese kittens that develop hypokalemia associated with disturbances in the intracellular and extracellular balance of potassium show the most severe myopathic signs. The syndrome in Burmese kittens (2 to 6 months of age) bears many similarities to hypokalemic periodic paralysis in humans, a condition that is thought to be related to a calcium channel disorder. The condition has a familial and inherited basis (putative autosomal-recessive), with affected kittens being produced in specific lines of this breed.

In the acquired disease dietary factors appear to contribute significantly to the development of hypokalemia and subsequent myopathy; potassium-depleted diets, acidifying diets, magnesium-restricted diets, and high-protein diets have been incriminated. In recent years pet food manufacturers have ensured that appropriate concentrations of minerals are added and that the formulation of diets for cats is not overacidifying. Primary

hyperaldosteronism (Conn's syndrome) caused by a functional tumor of the zona glomerulosa of the adrenal glands has been reported more frequently in aged cats. Both benign adenoma and adenocarcinoma have been found (Shiel and Mooney, 2007).

CLINICAL SIGNS

Whatever the cause of hypokalemia, the clinical signs shown by the affected cats are similar. The clinical signs may be transient or persistent. The earliest sign of severe potassium depletion is muscle dysfunction. There is generalized muscle weakness with persistent ventroflexion of the neck, with the head being tucked into the sternum (Fig. 247-1). The cats are intolerant of exercise; and some walk with an awkward, stiff, stilted gait. There may be exertional muscle tremor followed by sudden fatigue and collapse. Severely affected cats are reluctant to move, and some owners report that their cat showed lethargy and tiredness for some months before a severe episode occurred. Some cats show pain when their muscles are palpated. The clinical course in Burmese kittens is much more transient, with moderate-to-severe episodes followed by improvement (with or without treatment).

Box 247-1

Some Conditions Associated With Hypokalemia in Cats

- Acidified diets
- Chronic renal failure
- Chronic vomiting /diarrhea
- Diet—Potassium deficient or prolonged anorexia
- Diuretic therapy (furosemide)
- Fluid administration (plasma dilution and volume-induced diuresis)
- Hepatic disease
- Hyperaldosteronism (Conn's syndrome) caused by an adrenocortical tumor
- Idiopathic (Burmese breed)
- Infectious disease
- Insulin overdose
- Metabolic acidosis
- Metabolic alkalosis
- Potassium deficiency
- Renal tubular acidosis
- Systemic diseases
- Thyrotoxicosis

Fig. 247-1 A 9-month-old Burmese cat with hypokalemia and ventroflexion of the head.

and relapse. Postural reactions and spinal reflexes are normal.

Cats with advanced potassium depletion may show other signs, including poor body condition with weight loss; a poor, unkempt hair coat; and polydipsia and polyuria. These latter signs are mostly present in cats in which concurrent chronic renal failure is present.

Cats with Conn's syndrome may have concurrent hypertension with hypertensive cardiac, ocular, or neurological signs, or they may be asymptomatic.

DIAGNOSIS

The history, clinical findings, and breed (Burmese) provide a high index of suspicion of hypokalemia and the likely cause of potassium depletion.

The presence of low serum potassium, usually less than 3 mmol/L, confirms the diagnosis of hypokalemia; however, clinical signs occasionally can develop in cats with higher serum potassium values. Furthermore, serum potassium concentrations can increase after cage confinement or hospitalization because the myopathy and clinical signs are frequently precipitated or exacerbated by exercise. The low serum potassium concentration is frequently accompanied by increased serum activity (5,000 to 10,000 units/L) of serum creatine kinase (CK). The CK is released only when the concentration of potassium in muscle is very low. In affected Burmese kittens serum CK values can be very elevated (>50,000 units/L).

Other biochemical abnormalities that have been observed in hypokalemic cats include azotemia, hypercholesterolemia, hyperchloremia, hyperglycemia, and elevated serum creatinine. Such findings are frequently associated with concurrent renal dysfunction.

Elevation of blood pressure in conjunction with hypokalemia may suggest primary hyperaldosteronism. In such cases, ultrasonography of the adrenal glands is recommended and may detect unilateral adrenal enlargement, with or without local invasion or metastasis, if an aldosterone-secreting tumor is present.

Determination of the fractional excretion of potassium as ascertained by the formula that follows may help

differentiate renal and nonrenal sources of potassium loss. The FE_{K^+} should be less than 5% in a healthy cat with normal renal function and a potassium-depleted cat with normal renal function (e.g., in Burmese kittens with idiopathic hypokalemia). An FE_{K^+} of greater than 10% to 15% indicates significant renal potassium loss. Urinary loss may be determined more accurately by measuring the 24-hour urinary potassium loss.

$$FE_{K^+} (\%) = \frac{UK^+}{PK^+} \times \frac{PCr}{UCr} \times 100$$

where P = plasma, U = urine, Cr = creatinine, and K^+ = potassium.

The differential diagnosis of hypokalemic myopathy includes polyneuropathy, myasthenia gravis, organophosphate toxicity, thiamine deficiency, other electrolyte abnormalities, primary myopathies, tick paralysis, and snake bite.

Diffuse electromyographic abnormalities are sometimes present (e.g., positive sharp waves may be recorded). Muscle biopsy specimens are mostly normal on light microscopy, but mild myofiber necrosis is observed occasionally.

TREATMENT

The goal of treatment of the cat with hypokalemia and myopathic signs is to restore the serum potassium concentration to and maintain it in the reference range without causing the toxic side effects of potassium therapy. The clinical signs of muscle weakness are reversible, and the response to potassium supplementation is rapid. If potassium depletion is severe, potassium supplementation should be administered both orally and intravenously according to the dosage and administration rates detailed in Table 247-1. Intravenous potassium supplementation should not exceed 0.5 mmol(mEq)/kg/hr; otherwise cardiac dysrhythmias or asystole may occur. Electrocardiographic monitoring during therapy should be considered, and administration stopped if

Table 247-1

Intravenous Potassium Administration*

Serum Potassium (mmol/L)	Potassium Chloride Added to Fluids [†]	Maximum Volume Infusion Rate (ml/kg/hr) [‡]
3.6-5.0	20	25
3.1-3.5	30	17
2.6-3.0	40	12
2.1-2.5	60	8
<2.0	80	6

*Includes quantity and rate of administration not to exceed 0.5 mmol of potassium per liter per hour.

[†]mmol (mEq) of potassium per liter of crystalloid fluid; sufficient KCl should be added to achieve this concentration per liter.

[‡]Infusion rate of crystalloid (e.g., lactated Ringer's solution) containing supplemental KCl.

Note: Never inject KCl solutions intravenously.

dysrhythmias occur. It should be noted that in some cats the serum potassium may actually decline with intravenous fluid therapy, and frequent determinations should be made.

Once acute potassium depletion is corrected, oral treatment should be continued (see following paragraphs). If the cat is not severely affected, oral potassium supplementation is safe and effective for correcting clinical signs.

Potassium gluconate solution (Kaon Elixir, Adria Laboratories), tablets, or powder (Tumil K, Daniels Pharmaceuticals) can be administered in food. Potassium chloride is not an appropriate oral form of potassium because it can contribute to metabolic acidosis. A dosage rate of 2 to 4 mmol/cat/day orally is a safe and usually effective starting dosage. The serum potassium concentration should be rechecked every 10 to 14 days until serum values are stable in the reference range.

The link between renal disease and potassium depletion is well established; and, importantly, there is evidence that oral potassium supplementation will improve or stabilize the remaining renal function. Potassium depletion can contribute to ongoing renal damage; therefore cats with chronic renal failure should receive daily oral potassium supplementation (2 to 4 mmol/cat/day orally). Burmese kittens with transient periodic hypokalemia also benefit from daily oral supplementation.

If a diagnosis of hypokalemia is correct, the response to intravenous or oral potassium therapy is usually favorable and rapid (2 to 5 days). However, complete recovery of normal muscle strength in cats with myopathy can take up to several weeks. The prognosis is favorable with most affected cats, especially Burmese kittens, but the severity of the renal disease may alter that prognosis in some cats. In cats with Conn's syndrome the prognosis depends on identification and effective surgical treatment of the adrenal tumor. Preoperative stabilization of the hypokalemia and hypertension (if present) is required and important for optimal management. Concurrent therapy with spironolactone (2-4 mg PO q24h) and amlodopine (0.625-1.25 mg/cat, q24h) is recommended.

Pearls of the Ophthalmic Examination

DAVID J. MAGGS, *Davis, California*

Although signalment and historical data often provide essential clues to ocular diagnoses, ready visualization of almost all parts of the eye means that nothing can replace a complete examination. Fortunately a thorough ophthalmic examination is performed with just five requirements, five skills, and minimal equipment.

There are five essential requirements for a thorough ophthalmic examination:

1. Patient and veterinarian at eye level with each other
2. Dim ambient light
3. A bright and focal light source
4. A source of magnification
5. An orderly and complete approach

To minimize the extent to which the eyelids and orbital structures obscure the ocular structures, the patient should always be placed at eye level with the examining veterinarian. This is usually achieved simply by placing the patient on the examination table, which also limits patient movement. Having an assistant rather than the owner restrain the pet further reduces movement and is especially important when a detailed examination with magnification is performed. Since many structures within the normal eye are transparent, they are best examined in a darkened room using a very focal light source. This combination maximizes reflections, which are useful for examining ocular surfaces and enhance the examiner's ability to direct the light and their attention into the darker interior of the globe. Many ocular abnormalities are small and will be missed without a source of magnification and a bright light source. This combination can best be achieved in practice using an Optivisor head loupe and Finoff (Welch-Allyn) transilluminator. A readily available alternative is the otoscope used without the plastic cone. This provides a focal light source and approximately 2× to 3× magnification. Slit-lamp biomicroscopes are used by ophthalmologists and some general practitioners and maximize the combination of magnification and focal light source. By focusing the light to a narrow slit, an optical section provides microscopic detail in transparent ocular media such as the tear film, cornea, aqueous, lens, and vitreous.

The ophthalmic examination should be carried out in a repeatable and sequential manner to ensure that nothing is overlooked. A prepared examination sheet reminds the practitioner to perform all necessary tests in the correct sequence and permits lesions to be drawn. The examination begins by examining the patient from a distance for behavioral evidence of vision loss. The patient's head and

periocular tissues should then be more closely examined for facial symmetry, globe position and movement, periocular discharge, and overt ocular abnormalities. Brief but complete testing of the cranial nerves involved in normal ocular function follows. This should include tests of the menace response, palpebral reflex, pupillary light reflex, and dazzle reflex. More detailed examination of each eye is then performed.

Examining the unaffected eye before the affected eye in animals with unilateral disease ensures that the normal eye is not forgotten and provides information on each patient's normal ocular appearance.

Mastering the following five skills will provide all of the essential information from the anterior and posterior segments of the eye:

1. Retroillumination
2. Transillumination (or focal illumination)
3. Tonometry (measurement of intraocular pressure)
4. Assessment of aqueous flare
5. Fundic examination

Retroillumination is a simple but extremely useful technique for assessment of pupils and all parts of the transparent ocular media (tear film, cornea, aqueous, lens, and vitreous). A focal light source such as a Finoff transilluminator is held close to the examiner's eye and directed over the bridge of the patient's nose from at least arm's length (Fig. 248-1). Alternatively the direct ophthalmoscope can be held up against the examiner's eye (as for the fundic examination, see skill 5) but about arm's length from the patient. Either technique will elicit the fundic reflection, which is usually gold or green in tapetal animals or red in atapetal individuals. Because the examination is done at arm's length, each eye can be illuminated equally, and the fundic reflex can be used to assess and compare equality of pupil size and shape. In addition, opacities in any of the clear ocular media (e.g., corneal blood vessels, cataracts, vitreous debris) will obstruct the fundic reflection and are noted as black "shadows" against the fundic reflection. These opacities should be noted for subsequent and more detailed examination, with retroillumination repeated from close to the patient following pupil dilation. They should also be examined using transillumination and a source of magnification. Retroillumination is particularly useful for differentiating nuclear sclerosis from cataract.

Transillumination (sometimes called *focal illumination*) is then used to sequentially examine all ocular structures in front of and including the lens (the "anterior segment"). A focal light source should be directed at the eye from

Fig. 248-1 Retroillumination. A Finoff transilluminator is held close to the examiner's eye and directed over the bridge of the patient's nose from at least arm's length (**A**). The reflection from the animal's fundus is used to judge pupil size and the clarity of the ocular media. **B**, This patient has nuclear sclerosis visible as a subtle ring inside the pupil. (From Maggs DJ et al: *Slatter's fundamentals of veterinary ophthalmology*, ed 4, 2008, St. Louis, Saunders.)

many angles while the examiner simultaneously varies the viewing angle (Fig. 248-2). Varying the viewing and lighting angles relative to each other permits the examiner to use parallax, reflections, perspective, and shadows to gain valuable information regarding lesion depth. This technique is particularly useful for examining the anterior chamber since changes within this chamber can be more easily differentiated from corneal, iridal, or lenticular changes when viewed transversely. In cats the corneal curvature and anterior chamber depth are so great that limited visualization of the iridocorneal angle is also possible.

The importance of a sequential anterior segment examination cannot be overstated. An obvious method is to begin at the front and progress to the back of the eye while simultaneously moving from peripheral to axial. This ensures that the eyelids (including periocular skin, eyelid margin, and cilia), conjunctiva (third eyelid, bulbar, and palpebral conjunctival surfaces, as well as nasolacrimal puncta), sclera, cornea (including the limbus and tear film), anterior chamber, iris, pupil, and lens

are examined completely. Anterior segment examination should be initiated before dilation so that the iris face is easily examined; however, complete examination of the lens requires full dilation. The complete anterior segment should be examined using transillumination and a source of magnification such as the Optivisor, otoscope head, or a slit-lamp biomicroscope. Following pupil dilation, retroillumination can be repeated from close to the patient and with a source of magnification so that lesions in the clear ocular media can be both backlit and magnified without the pupil constricting. The otoscope head is particularly useful for this because the examiner can alter the viewing angle until the lesion is either backlit by the tapetal reflection dorsally or viewed against the dull nontapetal area of the fundus ventrally while illuminated from in front. In both cases the otoscope head is moved in or out from the eye until the lesion is in crisp focus and under full magnification against the chosen background.

Tonometry is the measurement of intraocular pressure (IOP) and is essential for differentiation of the two major vision-threatening conditions in which red eye is the

Fig. 248-2 Transillumination. A focal light source is directed at the eye from many angles while the examiner simultaneously varies the viewing angle. Varying the viewing and lighting angles relative to each other permits the examiner to use parallax, reflections, perspective, and shadows to gain valuable information regarding lesion depth.
